Overview of SAS Econometrics Procedures

SAS Econometrics procedures include predictive modeling tools that have been specially developed to take advantage of the distributed environment that SAS Viya provides. Methods include time series, compound distribution modeling, copula fitting and simulation, count data, panel data, limited dependent variables, spatial regression, economic capital modeling, hidden Markov models and severity modeling. In addition, these procedures provide many diagnostic tests, variable and model selection methods, visualization and distribution fitting comparisons that can help you to find the best model for your analysis.

NOTE: When you license SAS Econometrics, you also have access to SAS/ETS software. For more information about SAS/ETS procedures, see *SAS/ETS User's Guide*.

About This Book

This book assumes that you are familiar with Base SAS software and with the books *SAS Programmers Guide: Essentials* and *Base SAS Procedures Guide*. It also assumes that you are familiar with basic SAS System concepts, such as using the DATA step to create SAS data sets and using Base SAS procedures (such as the PRINT and SORT procedures) to manipulate SAS data sets.

Chapter Organization

This book contains the following chapters:

- **Chapter 1**, this chapter, provides an overview of SAS Econometrics procedures and summarizes related information, products, and services.
- **Chapter 4** provides information about topics that are common to multiple procedures. Topics include how to use SAS Cloud Analytic Services (CAS) sessions and how to load a SAS data set onto a CAS server. This chapter also documents the following statements that are used across a number of procedures: CLASS, DISPLAY, DISPLAYOUT, EFFECT, and SELECTION.
- Next are chapters that describe the procedures; they appear in alphabetical order by procedure name and are organized as follows:
 - The “Overview” section briefly describes the analysis provided by the procedure.
 - The “Getting Started” section provides a quick introduction to the procedure through a simple example.
 - The “Syntax” section describes the SAS statements and options that control the procedure.
 - The “Details” section discusses methodology and other topics, such as ODS tables.
 - The “Examples” section contains examples that use the procedure.
 - The “References” section contains references for the methodology.
- The last chapters in the book describe packages that you can use with the TSMODEL procedure. For more information about using packages, see *SAS Visual Forecasting: Time Series Packages*.

Typographical Conventions

This book uses several type styles for presenting information. The following list explains the meaning of the typographical conventions used in this book:

<i>roman</i>	is the standard type style used for most text.
UPPERCASE ROMAN	is used for SAS statements, options, and other SAS language elements when they appear in text. However, you can enter these elements in your own SAS programs in lowercase, uppercase, or a mixture of the two.
UPPERCASE BOLD	is used in the “Syntax” sections’ initial lists of SAS statements and options.
<i>oblique</i>	is used in the syntax definitions and in text to represent arguments for which you supply a value.
VariableName	is used for the names of variables and data sets when they appear in text.
bold	is used for matrices and vectors.
<i>italic</i>	is used for terms that are defined in text, for emphasis, and for references to publications.
monospace bold	is used for example code. In most cases, this book uses lowercase type for SAS code.

Options Used in Examples

The HTMLBLUE style is used to create the graphs and the HTML tables that appear in the online documentation. The PEARLJ style is used to create the PDF tables that appear in the documentation. A style template controls stylistic elements such as colors, fonts, and presentation attributes. You can specify a style template for an HTML ODS destination as follows:

```
ods html style=HTMLBlue;
```

You can also specify a style template for a PDF ODS destination as follows:

```
ods pdf style=PearlJ;
```

Most of the PDF tables are produced by using the following SAS System option:

```
options papersize=(6.5in 9in);
```

If you run the examples, you might get slightly different output. This is a function of the SAS System options that are used and the precision that your computer uses for floating-point calculations.

Overview

SAS Econometrics software provides Bayesian capabilities in three procedures: CQLIM, CNTSELECT, and SMC. The CQLIM and CNTSELECT procedures provide Bayesian analyses in addition to the standard frequentist analyses that they have always performed. PROC CQLIM enables you to perform Bayesian analysis of limited dependent variable models, and PROC CNTSELECT enables you to perform Bayesian analysis of count regression models. PROC SMC enables you to perform Bayesian analysis of nonlinear time series models by using sequential Monte Carlo methods.

This chapter provides an overview of Bayesian statistics; describes specific sampling algorithms used in these procedures; and discusses posterior inference and convergence diagnostics computations. Sources that provide in-depth treatment of Bayesian statistics can be found at the end of this chapter, in the section “A Bayesian Reading List” on page 39. Additional chapters contain syntax, details, and examples for the individual procedures CQLIM (see Chapter 12, “CQLIM Procedure”), CNTSELECT (see Chapter 10, “CNTSELECT Procedure”), and SMC (see Chapter 27, “SMC Procedure”).

Introduction

The most frequently used statistical methods are known as *frequentist* (or *classical*) methods. These methods assume that unknown parameters are fixed constants, and they define probability by using limiting relative frequencies. It follows from these assumptions that probabilities are objective and that you cannot make probabilistic statements about parameters because they are fixed. Bayesian methods offer an alternative approach; they treat parameters as random variables and define probability as “degrees of belief” (that is, the probability of an event is the degree to which you believe the event is true). It follows from these postulates that probabilities are subjective and that you can make probability statements about parameters. The term “Bayesian” comes from the prevalent usage of Bayes’ theorem, which was named after the Reverend Thomas Bayes, an 18th-century Presbyterian minister. Bayes was interested in solving the question of inverse probability: after observing a collection of events, what is the probability of one event?

Suppose you are interested in estimating θ from data $\mathbf{y} = \{y_1, \dots, y_n\}$ by using a statistical model described by the density $\pi(\mathbf{y}|\theta)$. Bayesian philosophy states that θ cannot be determined exactly, and uncertainty about the parameter is expressed through probability statements and distributions. You can say that θ follows a normal distribution with mean 0 and variance 1, if it is believed that this distribution best describes the uncertainty associated with the parameter. The following steps describe the essential elements of Bayesian inference:

1. A probability distribution for θ is formulated as $\pi(\theta)$, which is known as the *prior* distribution, or just the prior. The prior distribution expresses your beliefs (for example, on the mean, the spread, the skewness, and so forth) about the parameter before you examine the data.
2. Given the observed data $\mathbf{y}$, you choose the statistical model $\pi(\mathbf{y}|\theta)$ to describe the distribution of $\mathbf{y}$ given θ .
3. You update your beliefs about θ by combining information from the prior distribution and the data through the calculation of the *posterior* distribution, $\pi(\theta|\mathbf{y})$.

The third step is carried out by using Bayes’ theorem, which enables you to combine the prior distribution and the model in the following way:

$$\pi(\theta|\mathbf{y}) = \frac{\pi(\theta, \mathbf{y})}{\pi(\mathbf{y})} = \frac{\pi(\mathbf{y}|\theta)\pi(\theta)}{\pi(\mathbf{y})} = \frac{\pi(\mathbf{y}|\theta)\pi(\theta)}{\int \pi(\mathbf{y}|\theta)\pi(\theta)d\theta}$$

The quantity

$$\pi(\mathbf{y}) = \int \pi(\mathbf{y}|\theta)\pi(\theta)d\theta$$

is the normalizing constant of the posterior distribution. The quantity $\pi(\mathbf{y})$ is also the marginal distribution of $\mathbf{y}$, and it is sometimes called the marginal distribution of the data. The likelihood function of θ is any function proportional to $\pi(\mathbf{y}|\theta)$; that is, $L(\theta) \propto \pi(\mathbf{y}|\theta)$. Another way of writing Bayes’ theorem is as follows:

$$\pi(\theta|\mathbf{y}) = \frac{L(\theta)\pi(\theta)}{\int L(\theta)\pi(\theta)d\theta}$$

The marginal distribution $\pi(\mathbf{y})$ is an integral. As long as the integral is finite, the particular value of the integral does not provide any additional information about the posterior distribution. Hence, $\pi(\theta|\mathbf{y})$ can be written up to an arbitrary constant, presented here in proportional form as

$$\pi(\theta|\mathbf{y}) \propto L(\theta)\pi(\theta)$$

Simply put, Bayes' theorem tells you how to update existing knowledge with new information. You begin with a prior belief $\pi(\theta)$, and after learning information from data $\mathbf{y}$, you change or update your belief about θ and obtain $\pi(\theta|\mathbf{y})$. These are the essential elements of the Bayesian approach to data analysis.

In theory, Bayesian methods offer simple alternatives to statistical inference—all inferences follow from the posterior distribution $\pi(\theta|\mathbf{y})$. In practice, however, you can obtain the posterior distribution with straightforward analytical solutions only in the most rudimentary problems. Most Bayesian analyses require sophisticated computations, including the use of simulation methods, such as the Markov chain Monte Carlo (MCMC) methods. You generate samples from the posterior distribution and use these samples to estimate the quantities of interest. All SAS Econometrics procedures use a self-tuning random walk Metropolis (RWM) algorithm to generate these samples (see the sections “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 17 and “[Gibbs Sampler](#)” on page 18). An important aspect of any analysis is assessing the convergence of the Markov chains. Inferences that are based on nonconverged Markov chains can be both inaccurate and misleading.

Both Bayesian and classical methods have their advantages and disadvantages. From a practical point of view, your choice of method depends on what you want to accomplish with your data analysis. If you have prior information (either expert opinion or historical knowledge) that you want to incorporate into the analysis, then you should consider Bayesian methods. In addition, if you want to communicate your findings in terms of probability notions that can be more easily understood by nonstatisticians, Bayesian methods might be appropriate. The Bayesian paradigm can often provide a framework for answering specific scientific questions that a single point estimate cannot sufficiently address. Alternatively, if you are interested only in estimating parameters based on the likelihood, then numerical optimization methods, such as the Newton-Raphson method, can give you very precise estimates and there is no need to use a Bayesian analysis. For further discussions of the relative advantages and disadvantages of Bayesian analysis, see the section “[Bayesian Analysis: Advantages and Disadvantages](#)” on page 11.

Background in Bayesian Statistics

Prior Distributions

A prior distribution of a parameter is the probability distribution that represents your uncertainty about the parameter before the current data are examined. Multiplying the prior distribution and the likelihood function together leads to the posterior distribution of the parameter. You use the posterior distribution to carry out all inferences. You cannot carry out any Bayesian inference or perform any modeling without using a prior distribution.

Objective Priors versus Subjective Priors

Bayesian probability measures the degree of belief that you have in a random event. By this definition, probability is highly subjective. It follows that all priors are *subjective priors*. Not everyone agrees with this notion of subjectivity when it comes to specifying prior distributions. There has long been a desire to obtain results that are objectively valid. Within the Bayesian paradigm, this can be somewhat achieved by using prior distributions that are “objective” (that is, that have a minimal impact on the posterior distribution). Such distributions are called *objective* or *noninformative* priors (see the next section). However, while noninformative priors are very popular in some applications, they are not always easy to construct. See DeGroot and Schervish (2002, Section 1.2) and Press (2003, Section 2.2) for more information about interpretations of probability. See Berger (2006) and Goldstein (2006) for discussions about objective Bayesian versus subjective Bayesian analysis.

Noninformative Priors

Roughly speaking, a prior distribution is noninformative if the prior is “flat” relative to the likelihood function. Thus, a prior $\pi(\theta)$ is noninformative if it has minimal impact on the posterior distribution of θ . Other names for the noninformative prior are *vague*, *diffuse*, and *flat* prior. Many statisticians favor noninformative priors because they appear to be more objective. However, it is unrealistic to expect that noninformative priors represent total ignorance about the parameter of interest. In some cases, noninformative priors can lead to *improper posteriors* (nonintegrable posterior density). You cannot make inferences with improper posterior distributions. In addition, noninformative priors are often not invariant under transformation; that is, a prior might be noninformative in one parameterization but not necessarily noninformative if a transformation is applied.

See Box and Tiao (1973) for a more formal development of noninformative priors. See Kass and Wasserman (1996) for techniques for deriving noninformative priors.

Improper Priors

A prior $\pi(\theta)$ is said to be improper if

$$\int \pi(\theta) d\theta = \infty$$

For example, a uniform prior distribution on the real line, $\pi(\theta) \propto 1$, for $-\infty < \theta < \infty$, is an improper prior. Improper priors are often used in Bayesian inference since they usually yield noninformative priors

and proper posterior distributions. Improper prior distributions can lead to posterior impropriety (improper posterior distribution). To determine whether a posterior distribution is proper, you need to make sure that the normalizing constant $\int \pi(\mathbf{y}|\theta)\pi(\theta)d\theta$ is finite for all $\mathbf{y}$. If an improper prior distribution leads to an improper posterior distribution, inference based on the improper posterior distribution is invalid.

Both the CQLIM and CNTSELECT procedures allow the use of improper priors—that is, flat priors on the real line—for regression coefficients and other parameters. These improper priors can lead to improper posterior distributions, so you must ensure that they are proper.

Informative Priors

An informative prior is a prior that is not dominated by the likelihood and that has an impact on the posterior distribution. If a prior distribution dominates the likelihood, it is clearly an informative prior. These types of distributions must be specified with care in actual practice. On the other hand, the proper use of prior distributions illustrates the power of the Bayesian method: information gathered from the previous study, past experience, or expert opinion can be combined with current information in a natural way.

Conjugate Priors

A prior is said to be a conjugate prior for a family of distributions if the prior and posterior distributions are from the same family, which means that the form of the posterior has the same distributional form as the prior distribution. For example, if the likelihood is binomial, $y \sim \text{Bin}(n, \theta)$, a conjugate prior on θ is the beta distribution; it follows that the posterior distribution of θ is also a beta distribution. Other commonly used conjugate prior/likelihood combinations include the normal/normal, gamma/Poisson, gamma/gamma, and gamma/beta cases. The development of conjugate priors was partially driven by a desire for computational convenience—conjugacy provides a practical way to obtain the posterior distributions. The Bayesian procedures do not use conjugacy in posterior sampling.

Bayesian Inference

Bayesian inference about θ is primarily based on the posterior distribution of θ . There are various ways in which you can summarize this distribution. For example, you can report your findings through point estimates. You can also use the posterior distribution to construct hypothesis tests or probability statements.

Point Estimation and Estimation Error

Classical methods often report the maximum likelihood estimator (MLE) or the method of moments estimator (MOME) of a parameter. In contrast, Bayesian approaches often use the posterior mean. The definition of the posterior mean is given by

$$E(\theta|\mathbf{y}) = \int \theta \pi(\theta|\mathbf{y}) d\theta$$

Other commonly used posterior estimators include the posterior median, defined as

$$\theta: P(\theta \geq \text{median}|\mathbf{y}) = P(\theta \leq \text{median}|\mathbf{y}) = \frac{1}{2}$$

and the posterior mode, defined as the value of θ that maximizes $\pi(\theta|\mathbf{y})$.

The variance of the posterior density (simply referred to as the *posterior variance*) describes the uncertainty in the parameter, which is a random variable in the Bayesian paradigm. A Bayesian analysis typically uses the posterior variance, or the posterior standard deviation, to characterize the dispersion of the parameter. In multidimensional models, covariance or correlation matrices are used.

If you know the distributional form of the posterior density of interest, you can report the exact posterior point estimates. When models become too difficult to analyze analytically, you have to use simulation algorithms, such as the MCMC method to obtain posterior estimates (see the section “[Markov Chain Monte Carlo Method](#)” on page 16). All the Bayesian procedures rely on MCMC to obtain all posterior estimates. Using only a finite number of samples, simulations introduce an additional level of uncertainty to the accuracy of the estimates. *Monte Carlo standard error (MCSE)*, which is the standard error of the posterior mean estimate, measures the simulation accuracy. See the section “[Standard Error of the Mean Estimate](#)” on page 36 for more information.

The posterior standard deviation and the MCSE are two completely different concepts: the posterior standard deviation describes the uncertainty in the parameter, whereas the MCSE describes only the uncertainty in the parameter estimate as a result of MCMC simulation. The posterior standard deviation is a function of the sample size in the data set, and the MCSE is a function of the number of iterations in the simulation.

Hypothesis Testing

Suppose you have the following null and alternative hypotheses: H_0 is $\theta \in \Theta_0$ and H_1 is $\theta \in \Theta_0^c$, where Θ_0 is a subset of the parameter space and Θ_0^c is its complement. Using the posterior distribution $\pi(\theta|\mathbf{y})$, you can compute the posterior probabilities $P(\theta \in \Theta_0|\mathbf{y})$ and $P(\theta \in \Theta_0^c|\mathbf{y})$, or the probabilities that H_0 and H_1 are true, respectively. One way to perform a Bayesian hypothesis test is to accept the null hypothesis if $P(\theta \in \Theta_0|\mathbf{y}) \geq P(\theta \in \Theta_0^c|\mathbf{y})$ and vice versa, or to accept the null hypothesis if $P(\theta \in \Theta_0|\mathbf{y})$ is greater than a predefined threshold, such as 0.75, to guard against falsely accepted null distribution.

It is more difficult to carry out a point null hypothesis test in a Bayesian analysis. A point null hypothesis is a test of $H_0: \theta = \theta_0$ versus $H_1: \theta \neq \theta_0$. If the prior distribution $\pi(\theta)$ is a continuous density, then the posterior probability of the null hypothesis being true is 0, and there is no point in carrying out the test. One alternative is to restate the null to be a small interval hypothesis: $\theta \in \Theta_0 = (\theta_0 - a, \theta_0 + a)$, where a is a very small constant. The Bayesian paradigm can deal with an interval hypothesis more easily. Interval hypotheses can be tested in the CQLIM, CNTSELECT, and SMC procedures. For a more detailed treatment of Bayesian hypothesis testing, see Berger (1985).

Interval Estimation

The Bayesian set estimates are called *credible sets*, which are also known as *credible intervals*. This is analogous to the concept of confidence intervals used in classical statistics. Given the posterior distribution $\pi(\theta|\mathbf{y})$, A is a credible set for θ if

$$P(\theta \in A|\mathbf{y}) = \int_A \pi(\theta|\mathbf{y}) d\theta$$

For example, you can construct a 95% credible set for θ by finding an interval, A , over which $\int_A \pi(\theta|\mathbf{y}) = 0.95$.

You can construct credible sets that have equal tails. A $100(1 - \alpha)\%$ equal-tail interval corresponds to the $100(\alpha/2)$ th and $100(1 - \alpha/2)$ th percentiles of the posterior distribution. Some statisticians prefer this interval because it is invariant under transformations. Another frequently used Bayesian credible set is called the *highest posterior density* (HPD) interval.

A $100(1 - \alpha)\%$ HPD interval is a region that satisfies the following two conditions:

1. The posterior probability of that region is $100(1 - \alpha)\%$.
2. The minimum density of any point within that region is equal to or larger than the density of any point outside that region.

The HPD is an interval in which most of the distribution lies. Some statisticians prefer this interval because it is the smallest interval.

One major distinction between Bayesian and classical sets is their interpretation. The Bayesian probability reflects a person's subjective beliefs. Following this approach, a statistician can make the claim that θ is inside a credible interval with measurable probability. This property is appealing because it enables you to make a direct probability statement about parameters. Many people find this concept to be a more natural way of understanding a probability interval, which is also easier to explain to nonstatisticians. A confidence interval, on the other hand, enables you to make a claim that the interval covers the true parameter. The interpretation reflects the uncertainty in the sampling procedure; a confidence interval of $100(1 - \alpha)\%$ asserts that, in the long run, $100(1 - \alpha)\%$ of the realized confidence intervals cover the true parameter.

Bayesian Analysis: Advantages and Disadvantages

Bayesian methods and classical methods both have advantages and disadvantages, and there are some similarities. When the sample size is large, Bayesian inference often provides results for parametric models that are very similar to the results produced by frequentist methods. Advantages of using Bayesian analysis include the following:

- It provides a natural and principled way of combining prior information with data, within a solid decision theoretical framework. You can incorporate past information about a parameter and form a prior distribution for future analysis. When new observations become available, the previous posterior distribution can be used as a prior. All inferences logically follow from Bayes' theorem.
- It provides inferences that are conditional on the data and are exact, without reliance on asymptotic approximation. Small sample inference proceeds in the same manner as if one had a large sample. Bayesian analysis also can estimate any functions of parameters directly, without using the "plug-in" method (a way to estimate functionals by plugging the estimated parameters in the functionals).
- It obeys the likelihood principle. If two distinct sampling designs yield proportional likelihood functions for θ , then all inferences about θ should be identical from these two designs. Classical inference does not in general obey the likelihood principle.
- It provides interpretable answers, such as "the true parameter θ has a probability of 0.95 of falling in a 95% credible interval."

- It provides a convenient setting for a wide range of models, such as hierarchical models and missing data problems. MCMC, along with other numerical methods, makes computations tractable for virtually all parametric models.

There are also disadvantages to using Bayesian analysis:

- It does not tell you how to select a prior. There is no correct way to choose a prior. Bayesian inferences require skills to translate subjective prior beliefs into a mathematically formulated prior. If you do not proceed with caution, you can generate misleading results.
- It can produce posterior distributions that are heavily influenced by the priors. From a practical point of view, it might sometimes be difficult to convince subject matter experts who do not agree with the validity of the chosen prior.
- It often comes with a high computational cost, especially in models with a large number of parameters. In addition, simulations provide slightly different answers unless the same random seed is used. Note that slight variations in simulation results do not contradict the early claim that Bayesian inferences are exact. The posterior distribution of a parameter is exact, given the likelihood function and the priors, while simulation-based estimates of posterior quantities can vary due to the random number generator used in the procedures.

For more in-depth treatments of the pros and cons of Bayesian analysis, see Berger (1985, Sections 4.1 and 4.12), Berger and Wolpert (1988), Bernardo and Smith (1994, with a new edition coming out), Carlin and Louis (2000, Section 1.4), Robert (2001, Chapter 11), and Wasserman (2004, Section 11.9).

The following sections provide detailed information about the Bayesian methods provided in SAS.

Standard Prior Distributions

Table 2.1 through Table 2.10 show the density functions for all the distributions that you can use as priors in SAS Econometrics procedures. Some procedures support only a subset of these distributions. You can typically specify these distributions as priors for model parameters in a PRIOR statement.

Table 2.1 Beta Distribution

Density	$f(\theta a, b) = \frac{\theta^{a-1}(1-\theta)^{b-1}}{B(a, b)}$
Parameter restriction	$a > 0, \quad b > 0$
Range	$\begin{cases} \theta \in [0, 1] & \text{when } a = 1, b = 1 \\ \theta \in [0, 1] & \text{when } a = 1, b \neq 1 \\ \theta \in (0, 1] & \text{when } a \neq 1, b = 1 \\ \theta \in (0, 1) & \text{otherwise} \end{cases}$
Mean	$\frac{a}{a+b}$
Variance	$\frac{ab}{(a+b)^2(a+b+1)}$

Table 2.1 *continued*

Mode	$\left\{ \begin{array}{ll} \frac{a-1}{a+b-2} & a > 1, b > 1 \\ 0 \text{ and } 1 & a < 1, b < 1 \\ 0 & \left\{ \begin{array}{l} a < 1, b \geq 1 \\ a = 1, b > 1 \end{array} \right. \\ 1 & \left\{ \begin{array}{l} a \geq 1, b < 1 \\ a > 1, b = 1 \end{array} \right. \\ \text{not unique} & a = b = 1 \end{array} \right.$
------	--

Table 2.2 Cauchy Distribution

Density	$f(\theta \mu, \gamma) = \frac{1}{\pi\gamma \left[1 + \left(\frac{\theta-\mu}{\gamma}\right)^2\right]}$
Parameter restriction	$\gamma > 0$
Range	$\theta \in (-\infty, \infty)$
Mean	Not defined
Variance	Not defined
Mode	μ

Table 2.3 Gamma Distribution

Density	$f(\theta a, b) = \frac{1}{b^a \Gamma(a)} \theta^{a-1} e^{-\theta/b}$
Parameter restriction	$a > 0, b > 0$
Range	$\theta \in [0, \infty)$
Mean	ab
Variance	ab^2
Mode	$(a-1)b$

Table 2.4 Inverse Gamma Distribution

Density	$f(\theta a, b) = \frac{b^a}{\Gamma(a)} \theta^{-(a+1)} e^{-b/\theta}$
Parameter restriction	$a > 0, b > 0$
Range	$\theta \in [0, \infty)$
Mean	$\frac{b}{a-1}, \quad a > 1$

Table 2.4 *continued*

Variance	$\frac{b^2}{(a-1)^2(a-2)}, \quad a > 2$
Mode	$\frac{b}{a+1}$

Table 2.5 Lognormal Distribution

Density	$f(\theta \mu, \sigma) = \frac{1}{\theta\sigma\sqrt{2\pi}} \exp\left(-\frac{(\log \theta - \mu)^2}{2\sigma^2}\right)$
Parameter restriction	$\sigma > 0$
Range	$\theta \in (0, \infty)$
Mean	$\exp(\mu + \sigma^2/2)$
Variance	$\exp(2\mu + 2\sigma^2) - \exp(2\mu + \sigma^2)$
Mode	$\exp(\mu - \sigma^2)$

Table 2.6 Normal Distribution

Density	$f(\theta \mu, \sigma) = \frac{1}{\sigma\sqrt{2\pi}} \exp\left(-\frac{(\theta - \mu)^2}{2\sigma^2}\right)$
Parameter restriction	$\sigma > 0$
Range	$\theta \in (-\infty, \infty)$
Mean	μ
Variance	σ^2
Mode	μ

Table 2.7 Square Root Gamma Distribution

Density	$f(\theta a, b) = \frac{2}{b^a\Gamma(a)} \theta^{2a-1} e^{-\theta^2/b}$
Parameter restriction	$a > 0, b > 0$
Range	$\theta \in [0, \infty)$
Mean	$\frac{\Gamma(a+\frac{1}{2})}{\Gamma(a)} \sqrt{b}$
Variance	$\left\{ a - \left[\frac{\Gamma(a+\frac{1}{2})}{\Gamma(a)} \right]^2 \right\} b$
Mode	$\sqrt{(a - \frac{1}{2})b}, \quad a \geq \frac{1}{2}$

This is also known as the Nakagami distribution. For more information, see Stacy (1962).

Table 2.8 Square Root Inverse Gamma Distribution

Density	$f(\theta a, b) = \frac{2b^a}{\Gamma(a)} \theta^{-(2a+1)} e^{-b/\theta^2}$
Parameter restriction	$a > 0, b > 0$
Range	$\theta \in [0, \infty)$
Mean	$\frac{\Gamma(a-\frac{1}{2})}{\Gamma(a)} \sqrt{b}, \quad a > \frac{1}{2}$
Variance	$\left\{ \frac{1}{a-1} - \left[\frac{\Gamma(a-\frac{1}{2})}{\Gamma(a)} \right]^2 \right\} b, \quad a > 1$
Mode	$\sqrt{\frac{b}{a+\frac{1}{2}}}$

This is also known as the inverse Nakagami distribution. For more information, see Stacy (1962).

Table 2.9 t Distribution

Density	$f(\theta \mu, \sigma, \nu) = \frac{\Gamma(\frac{\nu+1}{2})}{\Gamma(\frac{\nu}{2})\sqrt{\pi\nu}\sigma} \left[1 + \frac{1}{\nu} \frac{(\theta-\mu)^2}{\sigma^2} \right]^{-\frac{\nu+1}{2}}$
Parameter restriction	$\sigma > 0, \nu > 0$
Range	$\theta \in (-\infty, \infty)$
Mean	$\mu, \text{ for } \nu > 1$
Variance	$\frac{\nu}{\nu-2} \sigma^2, \text{ for } \nu > 2$
Mode	μ

Table 2.10 Uniform Distribution

Density	$f(\theta m, M) = \frac{1}{M-m}$
Parameter restriction	$-\infty < m < M < \infty$
Range	$\theta \in [m, M]$
Mean	$\frac{m+M}{2}$
Variance	$\frac{(M-m)^2}{12}$
Mode	Not unique

Some procedures allow for improper uniform priors, where $m = -\infty$ or $M = \infty$. For more information, see the section “[Improper Priors](#)” on page 8.

Markov Chain Monte Carlo Method

The Markov chain Monte Carlo (MCMC) method is a general simulation method for sampling from posterior distributions and computing posterior quantities of interest. MCMC methods sample successively from a target distribution. Each sample depends on the previous one, hence the notion of the Markov chain. A Markov chain is a sequence of random variables, $\theta^1, \theta^2, \dots$, for which the random variable θ^t depends on all previous θ s only through its immediate predecessor θ^{t-1} . You can think of a Markov chain applied to sampling as a mechanism that traverses randomly through a target distribution without having any memory of where it has been. Where it moves next is entirely dependent on where it is now.

Monte Carlo, as in Monte Carlo integration, is mainly used to approximate an expectation by using the Markov chain samples. In the simplest version

$$\int_S g(\theta) p(\theta) d\theta \cong \frac{1}{n} \sum_{t=1}^n g(\theta^t)$$

where $g(\cdot)$ is a function of interest and θ^t are samples from $p(\theta)$ on its support S . This approximates the expected value of $g(\theta)$. The earliest reference to MCMC simulation occurs in the physics literature. Metropolis and Ulam (1949) and Metropolis et al. (1953) describe what is known as the Metropolis algorithm (see the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 17). The algorithm can be used to generate sequences of samples from the joint distribution of multiple variables, and it is the foundation of MCMC. Hastings (1970) generalized their work, resulting in the Metropolis-Hastings algorithm. Geman and Geman (1984) analyzed image data by using what is now called Gibbs sampling (see the section “[Gibbs Sampler](#)” on page 18). These MCMC methods first appeared in the mainstream statistical literature in Tanner and Wong (1987).

The Markov chain method has been quite successful in modern Bayesian computing. Only in the simplest Bayesian models can you recognize the analytical forms of the posterior distributions and summarize inferences directly. In moderately complex models, posterior densities are too difficult to work with directly. With the MCMC method, it is possible to generate samples from an arbitrary posterior density, $\pi(\theta|\mathbf{y})$, and to use these samples to approximate expectations of quantities of interest. Several other aspects of the Markov chain method also contributed to its success. Most importantly, if the simulation algorithm is implemented correctly, the Markov chain is guaranteed to converge to the target distribution $\pi(\theta|\mathbf{y})$ under rather broad conditions, regardless of where the chain was initialized. In other words, a Markov chain is able to improve its approximation to the true distribution at each step in the simulation. Furthermore, if the chain is run for a very long time (often required), you can recover $\pi(\theta|\mathbf{y})$ to any precision. Also, the simulation algorithm is easily extensible to models with a large number of parameters or high complexity, although the “curse of dimensionality” often causes problems in practice.

Properties of Markov chains are discussed in Feller (1968), Breiman (1968), and Meyn and Tweedie (1993). Ross (1997) and Karlin and Taylor (1975) give a non-measure-theoretic treatment of stochastic processes, including Markov chains. For conditions that govern Markov chain convergence and rates of convergence, see Amit (1991), Applegate, Kannan, and Polson (1990), Chan (1993), Geman and Geman (1984), Liu, Wong, and Kong (1991a, b), Rosenthal (1991a, b), Tierney (1994), and Schervish and Carlin (1992). Besag (1974) describes conditions under which a set of conditional distributions gives a unique joint distribution. Tanner (1993), Gilks, Richardson, and Spiegelhalter (1996), Chen, Shao, and Ibrahim (2000), Liu (2001), Gelman et al. (2004), Robert and Casella (2004), and Congdon (2001, 2003, 2005) provide both theoretical

and applied treatments of MCMC methods. You can also see the section “A Bayesian Reading List” on page 39 for a list of books with varying levels of difficulty of treatment of the subject and its application to Bayesian statistics.

Metropolis and Metropolis-Hastings Algorithms

The Metropolis algorithm is named after its inventor, the American physicist and computer scientist Nicholas C. Metropolis. The algorithm is simple but practical, and it can be used to obtain random samples from any arbitrarily complicated target distribution of any dimension that is known up to a normalizing constant.

Suppose you want to obtain T samples from a univariate distribution with the probability density function $\pi(\theta|y)$. Suppose θ^t is the t th sample from f . To use the Metropolis algorithm, you need to have an initial value θ^0 and a symmetric *proposal* density $q(\theta^{\text{prop}}|\theta^t)$. For the $(t + 1)$ iteration, the algorithm generates a proposal sample θ^{prop} from $q(\cdot|\cdot)$ that is based on the current sample θ^t , and it makes a decision to either accept or reject the new sample. If the new sample is accepted, the algorithm repeats itself by starting at the new sample. If the new sample is rejected, the algorithm starts at the current point and repeats. The algorithm is self-repeating, so it can be carried out as long as required. In practice, you have to decide the total number of samples needed in advance and stop the sampler after that many iterations have been completed.

Suppose that $q(\theta^{\text{prop}}|\theta^t)$ is a symmetric distribution. The proposal distribution should be an easy distribution from which to sample, and it must be such that $q(\theta^{\text{prop}}|\theta^t) = q(\theta^t|\theta^{\text{prop}})$, meaning that the likelihood of jumping to θ^{prop} from θ^t is the same as the likelihood of jumping back to θ^t from θ^{prop} . The most common choice of the proposal distribution is the normal distribution $N(\theta^t, \sigma)$ with a fixed σ . This is called a random walk Metropolis algorithm (RWM) and can be summarized as follows:

1. Set $t = 0$. Choose a starting point θ^0 . This can be an arbitrary point as long as $\pi(\theta^0|y) > 0$.
2. Generate a new sample, θ^{prop} , by using the proposal distribution $q(\cdot|\theta^t)$.
3. Calculate the following quantity:

$$r = \min \left\{ \frac{\pi(\theta^{\text{prop}}|y)}{\pi(\theta^t|y)}, 1 \right\}$$

4. Sample u from the uniform distribution $U(0, 1)$.
5. Set $\theta^{t+1} = \theta^{\text{prop}}$ if $u < r$; otherwise set $\theta^{t+1} = \theta^t$.
6. Set $t = t + 1$. If $t < n$, the number of desired samples, return to step 2. Otherwise, stop.

Note that the iteration number keeps increasing regardless of whether a proposed sample is accepted.

This algorithm defines a chain of random variates whose distribution will converge to the desired distribution, $\pi(\theta|y)$, and so from some point forward, the chain of samples is a sample from the distribution of interest. In Markov chain terminology, this distribution is called the *stationary distribution* of the chain, and in Bayesian statistics, it is the posterior distribution of the model parameters. The reason that the Metropolis algorithm works is beyond the scope of this documentation, but you can find more detailed descriptions and proofs in many standard textbooks, including Roberts (1996) and Liu (2001). The random walk Metropolis algorithm is used by all SAS Econometrics procedures that provide Bayesian inference.

You are not limited to a symmetric random walk proposal distribution in establishing a valid sampling algorithm. A more general form, the Metropolis-Hastings (MH) algorithm, was proposed by Hastings (1970). The MH algorithm uses an asymmetric proposal distribution: $q(\theta^{\text{prop}}|\theta^t) \neq q(\theta^t|\theta^{\text{prop}})$. The difference in its implementation comes in calculating the ratio of densities:

$$r = \min \left\{ \frac{\pi(\theta^{\text{prop}}|\mathbf{y})q(\theta^t|\theta^{\text{prop}})}{\pi(\theta^t|\mathbf{y})q(\theta^{\text{prop}}|\theta^t)}, 1 \right\}$$

Other steps remain the same.

The extension of the Metropolis algorithm to a higher-dimensional θ is straightforward. Suppose that $\theta = (\theta_1, \theta_2, \dots, \theta_k)'$ is the parameter vector. To start the Metropolis algorithm, select an initial value for each θ_k and use a multivariate version of proposal distribution $q(\cdot|\cdot)$, such as a multivariate normal distribution, to select a k -dimensional new parameter. Other steps remain the same as those previously described, and this Markov chain eventually converges to the target distribution of $\pi(\theta|\mathbf{y})$. Chib and Greenberg (1995) provide a useful tutorial on the algorithm.

Gibbs Sampler

The Gibbs sampler, named by Geman and Geman (1984) after the American physicist Josiah W. Gibbs, is a special case of the “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 17 in which the proposal distributions exactly match the posterior conditional distributions and proposals are accepted 100% of the time. Gibbs sampling requires you to decompose the joint posterior distribution into full conditional distributions for each parameter in the model and then sample from them. The sampler can be efficient when the parameters are not highly dependent on each other and the full conditional distributions are easy to sample from. Some researchers favor this algorithm because it does not require an instrumental proposal distribution as Metropolis methods do. However, while deriving the conditional distributions can be relatively easy, it is not always possible to find an efficient way to sample from these conditional distributions.

Suppose that $\theta = (\theta_1, \dots, \theta_k)'$ is the parameter vector, $\pi(\mathbf{y}|\theta)$ is the likelihood, and $\pi(\theta)$ is the prior distribution. The full posterior conditional distribution of $\pi(\theta_i|\theta_j, i \neq j, \mathbf{y})$ is proportional to the joint posterior density; that is,

$$\pi(\theta_i|\theta_j, i \neq j, \mathbf{y}) \propto \pi(\mathbf{y}|\theta)\pi(\theta)$$

For instance, the one-dimensional conditional distribution of θ_1 given $\theta_j = \theta_j^*, 2 \leq j \leq k$, is computed as the following:

$$\pi(\theta_1|\theta_j = \theta_j^*, 2 \leq j \leq k, \mathbf{y}) = \pi(\mathbf{y}|\theta = (\theta_1, \theta_2^*, \dots, \theta_k^*)')\pi(\theta = (\theta_1, \theta_2^*, \dots, \theta_k^*)')$$

The Gibbs sampler works as follows:

1. Set $t = 0$, and choose an arbitrary initial value of $\theta^0 = \{\theta_1^0, \dots, \theta_k^0\}$.
2. Generate each component of θ as follows:

- Draw θ_1^{t+1} from $\pi(\theta_1|\theta_2^t, \dots, \theta_k^t, \mathbf{y})$
 - Draw θ_2^{t+1} from $\pi(\theta_2|\theta_1^{t+1}, \theta_3^t, \dots, \theta_k^t, \mathbf{y})$
 - $\vdots$
 - Draw θ_k^{t+1} from $\pi(\theta_k|\theta_1^{t+1}, \dots, \theta_{k-1}^{t+1}, \mathbf{y})$
3. Set $t = t + 1$. If $t < T$, the number of desired samples, return to step 2. Otherwise, stop.

The Gibbs sampler can draw more than one parameter simultaneously in each step. The grouped parameters are called blocks, and each parameter must belong to exactly one block. A block that contains only one parameter is called a scalar block. The blocks are drawn one at a time, but parameters in the same block are drawn from their joint full conditional distribution. For example, if θ_1 and θ_2 are in the same block, then they are drawn from $\pi(\theta_1, \theta_2|\theta_3^t, \dots, \theta_k^t, \mathbf{y})$. To maximize the Gibbs sampler's efficiency, parameters with high posterior correlation should be put in the same block.

Often not all the full conditional distributions in a Gibbs sampler are tractable, or easy to draw a random sample from. A common strategy for overcoming this problem is to use a Metropolis step to draw from the troublesome full conditionals, applying the ideas of the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 17 to a conditional posterior. This is known as Metropolis within Gibbs, and it is valid even if every step of the Gibbs sampler is a Metropolis step.

The name “Gibbs” was introduced by Geman and Geman (1984). Gelfand et al. (1990) first used Gibbs sampling to solve problems in Bayesian inference. See Casella and George (1992) for a tutorial on the sampler.

Tuning Random Walk Metropolis Algorithms

The efficiency of random walk Metropolis algorithms depends crucially on the proposal distribution. Finding a good proposal distribution for each block of parameters is called tuning. The proposal distribution must be tuned during a tuning phase before MCMC iterations are collected for posterior inference so that the tuning process does not bias posterior inference. Collectively, the tuning and burn-in phases are called the warmup phase. This section describes the tuning algorithm that is used for all RWM samplers employed in SAS Econometrics procedures.

A good proposal distribution should resemble the actual posterior distribution of the parameters. Large-sample theory states that the posterior distribution of the parameters approaches a multivariate normal distribution with a covariance matrix equal to the inverse of the negative Hessian of the log posterior at the posterior mode (Gelman et al. 2004, Appendix B; Schervish 1995, Section 7.4). That is why a normal proposal distribution often works well in practice. The proposal distribution for random walk Metropolis in SAS Econometrics procedures is always the normal distribution. It is generated in the following fashion:

$$\theta^{\text{prop}} \sim N(\theta^{\text{cur}}, c^{\text{cur}} \text{COV}^{\text{cur}})$$

where θ^{prop} is the proposed parameter vector, θ^{cur} is the previous value of the parameters in the Markov chain, c^{cur} is a scale parameter that is tuned in the tuning phase of the algorithm, and COV^{cur} is an approximation of the posterior covariance that is also tuned in the tuning phase of the algorithm. When there are multiple parameter blocks—that is, in a [Metropolis within Gibbs](#) scheme—each block is tuned separately, each with its own c^{cur} and COV^{cur} . In particular for a scalar block, COV^{cur} is also a scalar—an approximation to the posterior variance of the only parameter in that block.

The tuning phase consists of n_{stage} tuning stages, each n_{tune} iterations long. Between tuning stages, two sorts of adjustments to the proposal distribution are made: adjustments to the scale parameter c^{cur} and adjustments to the proposal covariance matrix COV^{cur} .

Scale Tuning

The acceptance rate of a Metropolis chain is closely related to its sampling efficiency. For a random walk Metropolis algorithm, a high acceptance rate means that most new samples occur right around the current parameter value. Their frequent acceptance means that the Markov chain is moving rather slowly and not fully exploring the parameter space. A low acceptance rate means that the proposed samples are often rejected; hence the chain is not moving much. An efficient random walk Metropolis sampler has an acceptance rate that is neither too high nor too low. The scale parameter c^{cur} in the proposal distribution effectively controls this acceptance probability. Roberts, Gelman, and Gilks (1997) show that if both the target density and the proposal density are normal, the optimal acceptance probability for the Markov chain should be around 0.45 in a one-dimensional problem and should asymptotically approach 0.234 in higher-dimensional problems. The corresponding optimal scale is 2.38.

Because of the nature of stochastic simulations, it is impossible to fine-tune a set of variables so that the Metropolis chain has exactly the target acceptance rate that you want. In addition, Roberts and Rosenthal (2001) empirically demonstrate that an acceptance rate between 0.15 and 0.5 is at least 80% efficient, so there is really no need to fine-tune the algorithms to reach an acceptance probability that is within a small tolerance of the optimal values. SAS Econometrics procedures tune the scale parameter so that the observed acceptance rate falls within some tolerance of the target acceptance rate. Let p^{obs} denote the observed acceptance rate in a given tuning stage, let δ denote the target acceptance rate, and let ϵ denote the tolerance. Then if $p^{\text{obs}} < \delta - \epsilon$, the value of c^{cur} is decreased. On the other hand, if $p^{\text{obs}} > \delta + \epsilon$, then the value of c^{cur} is increased. Typically $\epsilon = 0.075$ is a good choice, $\delta = 0.45$ is a good choice for blocks of parameters larger than three or four dimensions, and $\delta = 0.234$ is a good choice for scalar blocks.

When c^{cur} is adjusted between tuning stages, it is done using the following scheme:¹

$$c^{\text{new}} = \frac{c^{\text{cur}} \cdot \Phi^{-1}(\delta/2)}{\Phi^{-1}(p^{\text{obs}}/2)}$$

where c^{cur} is the scale from the previous tuning stage; c^{new} is the new scale for the next stage or any further sampling; p^{obs} is the observed acceptance rate in the previous tuning stage; and δ is the target acceptance rate. A good choice for the initial value of c^{cur} is 2.38 because it is optimal for a normal model with a normal proposal.

Covariance Tuning

When the proposal scale parameter is adjusted between stages, the proposal covariance matrix is also adjusted. To do this, SAS Econometrics procedures take a weighted average of the previously used covariance matrix and the observed covariance matrix in the last tuning stage. The formula to update the covariance matrix is

$$\text{COV}^{\text{new}} = w \text{COV}^{\text{obs}} + (1 - w) \text{COV}^{\text{cur}}$$

¹ Roberts, Gelman, and Gilks (1997) and Roberts and Rosenthal (2001) demonstrate that the relationship between acceptance probability and scale in a random walk Metropolis scheme is $p = 2\Phi(-\sqrt{I}c/2)$, where c is the scale; p is the acceptance rate; Φ is the cumulative distribution function of a standard normal distribution; and $I \equiv E_f[(f'(x)/f(x))^2]$, where $f(x)$ is the density function of samples. This relationship determines the updating scheme, with I replaced by the identity matrix to simplify calculation.

where w is the tuning weight, between 0 and 1; COV^{cur} is the covariance matrix that was used in the previous tuning stage; COV^{obs} is the covariance matrix that was observed in the previous tuning stage; and COV^{new} is the new covariance matrix that will be used for the next tuning stage or any further sampling. Larger weights cause the sampler to adapt the proposal covariance matrix faster during the tuning process, but if this value is too large, the sampler might never settle into a good choice. Typically, a good tuning weight is $w = 0.75$. If the initial value of COV^{cur} is very different from the posterior covariance matrix, many tuning stages might be required before the proposal distribution becomes efficient, because the Markov chain needs to spend time learning about the posterior covariance structure. If the proposal distribution is too different from the posterior, then the sampler can reject 100% of the time and tuning will not work. A good default choice for the initial value of the proposal covariance matrix, COV^{cur} , is the covariance matrix of the maximum likelihood estimates of the parameters, or the negative inverse Hessian of the log posterior density, if either is available.

Hamiltonian Monte Carlo Sampler

The Hamiltonian Monte Carlo (HMC) sampler, also known as the hybrid Monte Carlo sampler, is a version of the Metropolis algorithm that uses gradient information and auxiliary momentum variables to construct a Markov chain that converges to the posterior distribution (Neal 2011; Hoffman and Gelman 2014; Betancourt 2018). The algorithm uses Hamiltonian dynamics to construct distant Metropolis proposals, allowing it to converge quickly and to be efficient in many scenarios. HMC is applicable only to continuous unconstrained parameters, although constrained parameters can be transformed prior to sampling.

Suppose that $\boldsymbol{\theta} = (\theta_1, \theta_2, \dots, \theta_k)$ is the unknown parameter vector with the posterior distribution $\pi(\boldsymbol{\theta} | \mathbf{y})$, also known as the position vector. To define Hamiltonian dynamics, first define an auxiliary momentum vector $\mathbf{r} = (r_1, r_2, \dots, r_k)$ with probability density $q(\mathbf{r})$. Assume that $\mathbf{r} \sim N(\mathbf{0}, \mathbf{M})$, where $\mathbf{M}$ is also known as the mass matrix. Next, define potential energy as $V(\boldsymbol{\theta}) = -\log \pi(\boldsymbol{\theta} | \mathbf{y})$; kinetic energy as $T(\mathbf{r}) = -\log \pi(\mathbf{r}) = \text{constant} + \frac{1}{2}\mathbf{r}'\mathbf{M}^{-1}\mathbf{r}$; and total energy, also known as the Hamiltonian, as $H(\boldsymbol{\theta}, \mathbf{r}) = V(\boldsymbol{\theta}) + T(\mathbf{r})$. Finally, Hamilton's equations define the evolution of position and momentum in time as a physical system, given by

$$\frac{d\mathbf{r}}{d\tau} = -\frac{\partial H}{\partial \boldsymbol{\theta}} \quad \text{and} \quad \frac{d\boldsymbol{\theta}}{d\tau} = \frac{\partial H}{\partial \mathbf{r}}$$

where τ represents time in the system. A solution to these equations is called a Hamiltonian flow, or a Hamiltonian trajectory.

An idealized version of HMC samples $\boldsymbol{\theta}^{t+1}$ conditional on $\boldsymbol{\theta}^t$ as follows:

1. Sample an initial momentum, $\mathbf{r}' \sim N(\mathbf{0}, \mathbf{M})$.
2. Run the Hamiltonian flow from the initial position-momentum pair $(\boldsymbol{\theta}^0, \mathbf{r}^0) = (\boldsymbol{\theta}^t, \mathbf{r}')$, until some integration time $\mathcal{T}$ is reached, to obtain $(\boldsymbol{\theta}^{\mathcal{T}}, \mathbf{r}^{\mathcal{T}})$.
3. Set the next iteration of the Markov chain to the endpoint of the Hamiltonian flow, $\boldsymbol{\theta}^{t+1} = \boldsymbol{\theta}^{\mathcal{T}}$.

Hamiltonian flow conserves both total energy and volume of the system, and as a result, this Markov chain converges to the posterior distribution.

In practice, this algorithm cannot be used, because Hamilton's equations cannot be solved analytically, and instead they must be numerically integrated using leapfrog integration. Define a step size $\epsilon > 0$; let $l = 1, 2, \dots, L$ index leapfrog steps; and let $(\boldsymbol{\theta}^l, \mathbf{r}^l)$ denote the position-momentum pair at leapfrog step l ,

with the initial position-momentum pair $(\boldsymbol{\theta}^0, \mathbf{r}^0)$. Then a leapfrog step obtains $(\boldsymbol{\theta}^{l+1}, \mathbf{r}^{l+1})$ from $(\boldsymbol{\theta}^l, \mathbf{r}^l)$ via the following three steps:

$$\begin{aligned}\mathbf{r}^{l+1/2} &= \mathbf{r}^l - \frac{\epsilon}{2} \nabla V(\boldsymbol{\theta}^l) \\ \boldsymbol{\theta}^{l+1} &= \boldsymbol{\theta}^l + \epsilon \mathbf{M}^{-1} \mathbf{r}^{l+1/2} \\ \mathbf{r}^{l+1} &= \mathbf{r}^{l+1/2} - \frac{\epsilon}{2} \nabla V(\boldsymbol{\theta}^{l+1})\end{aligned}$$

where $\nabla V(\boldsymbol{\theta})$ is the gradient of the potential energy with respect to $\boldsymbol{\theta}$. The number of leapfrog steps is chosen on the basis of the desired integration time via $L = \lfloor \mathcal{T}/\epsilon \rfloor$, where $\lfloor x \rfloor$ rounds x down to the nearest integer.

Leapfrog integration exactly conserves volume but only approximately conserves energy, so in practice HMC uses a Metropolis correction to account for the error. To ensure that the Markov transition is reversible, you must reverse the sign of the momentum vector so that running the Hamiltonian flow from the endpoint returns it to the starting point. Accounting for all of this yields the HMC algorithm, which obtains iteration $\boldsymbol{\theta}^{t+1}$ from iteration $\boldsymbol{\theta}^t$ as follows:

1. Sample an initial momentum, $\mathbf{r}' \sim \mathcal{N}(\mathbf{0}, \mathbf{M})$.
2. Take $L = \lfloor \mathcal{T}/\epsilon \rfloor$ leapfrog steps from the initial position-momentum pair $(\boldsymbol{\theta}^0, \mathbf{r}^0) = (\boldsymbol{\theta}^t, \mathbf{r}')$ to obtain $(\boldsymbol{\theta}^L, \mathbf{r}^L)$.
3. Set $\boldsymbol{\theta}^{\text{prop}} = \boldsymbol{\theta}^L$ and $\mathbf{r}^{\text{prop}} = -\mathbf{r}^L$ and compute the Metropolis acceptance probability:

$$\begin{aligned}r &= \min \left\{ \exp \left[-H(\boldsymbol{\theta}^{\text{prop}}, \mathbf{r}^{\text{prop}}) + H(\boldsymbol{\theta}^0, \mathbf{r}^0) \right], 1 \right\} \\ &= \min \left\{ \exp \left[-H(\boldsymbol{\theta}^L, -\mathbf{r}^L) + H(\boldsymbol{\theta}^0, \mathbf{r}^0) \right], 1 \right\}\end{aligned}$$

4. With probability, r set $\boldsymbol{\theta}^{t+1} = \boldsymbol{\theta}^{\text{prop}}$; otherwise set $\boldsymbol{\theta}^{t+1} = \boldsymbol{\theta}^t$.

No-U-Turn Sampler

HMC can rapidly converge to the posterior distribution and can provide nearly iid draws, but it relies heavily on the careful choice of tuning parameters: the mass matrix $\mathbf{M}$, the step size $\epsilon > 0$, and the integration time $\mathcal{T} > 0$. The No-U-Turn Sampler (NUTS; Hoffman and Gelman 2014) solves part of this problem.

NUTS chooses the integration time dynamically—that is, based on the current position-momentum pair—and this is where the name comes from. To do this, it builds two Hamiltonian trajectories: a forward trajectory that moves forward from the initial position-momentum pair, and a backward trajectory that moves backward from the initial position-momentum pair. NUTS builds these trajectories recursively by using a binary tree as follows. Let $j = 0, 1, \dots, J_{\max}$ index the current height of the tree, where $J_{\max} > 0$ is the maximum height allowed.

1. Start at $j = 0$.
2. Flip a coin. If the result is heads, add 2^j leapfrog steps to the end of the forward trajectory. If the result is tails, add 2^j leapfrog steps to the end of the backward trajectory.
3. Set $j = j + 1$.

Then NUTS chooses to stop leapfrog integration when the trajectories start to make a “U-turn”—that is, when the endpoints of the two trajectories begin to move closer together.

Additionally, NUTS proposes all points in both the forward and backward trajectories simultaneously in the Metropolis step. If the step accepts, then NUTS uses a slice sampler to choose a single point from the combined trajectories. See Hoffman and Gelman (2014) for the details of how this works.

As the height of the tree increases, the computational cost of the iteration increases dramatically. As a result, NUTS caps the height of the tree at a maximum height of $J_{\max} > 0$. When an iteration reaches the maximum tree height, NUTS prematurely stops integration and proposes the current available forward and backward trajectories even if it has not made a U-turn. When NUTS reaches the maximum tree height for multiple iterations, this increases autocorrelation in the chain and leads to worse mixing. This is mainly a problem during sampling and not during warmup (tuning and burn-in). You can increase the maximum tree height to reduce these problems at the cost of increased computation per iteration. You can also force NUTS to cancel sampling if the maximum tree height is reached too many times.

The CQLIM and CNTSELECT procedures give you the option to use an implementation of the NUTS algorithm to draw the posterior samples.

Tuning for NUTS

The final two tuning parameters in HMC are the leapfrog integrator step size and the mass matrix. These can both be tuned during a tuning phase. NUTS tunes the step size throughout this tuning phase to achieve a target Metropolis acceptance rate of $0 < \delta < 1$ (usually set to 0.8), using a dual averaging optimization scheme. Smaller step sizes yield higher acceptance rates and a more robust algorithm with a higher computational cost per Markov chain iteration, whereas the opposite occurs for larger step sizes. So the target acceptance rate is chosen to balance computational cost and robustness, with larger values resulting in a more robust and more computationally costly NUTS algorithm.

NUTS does not tune the mass matrix, although it can be combined with a variety of mass matrix tuning algorithms. Typically the mass matrix is constant; this is known as Euclidean HMC. The alternative is to allow the mass matrix to depend on θ ; this is known as Riemannian HMC. Theory suggests that the ideal mass matrix in Euclidean HMC is the inverse posterior covariance matrix (Betancourt 2018). A diagonal mass matrix often yields a more efficient HMC or NUTS algorithm, but at the cost of robustness. In that case, the ideal mass matrix is the diagonal matrix of inverse posterior variances. In general, the posterior variances are unknown prior to sampling, so they must be estimated on the fly during an initial tuning phase.

The CQLIM and CNTSELECT procedures use a constant diagonal mass matrix for NUTS, and they have the ability to use a flexible class of tuning algorithms, known as expanding-window tuning algorithms, to learn the posterior variances. Let $n_{\text{tune}} \geq 0$ denote the number of tuning iterations available in the tuning phase. Next, divide the tuning phase into K windows. Let $k = 1, 2, \dots, K$ index windows, and let $n_k \geq 0$ denote the number of iterations that are apportioned to window k . Then $n_{\text{tune}} = \sum_{k=1}^K n_k$. The step size is tuned through each of these tuning windows, with no change to how it is tuned between windows, but the windows determine how to tune the mass matrix.

In the first tuning window, *only* the step size is tuned, and the initial mass matrix is used for sampling throughout. This allows the Markov chain to converge to the posterior distribution before the tuning algorithm attempts to estimate the posterior variances. Similarly, only the step size is tuned in the final window, and the mass matrix that is arrived at after tuning window n_{K-1} is used for sampling in the final tuning window, as well as after the tuning phase. This allows the step size to be adapted to the final mass matrix. Both the initial window size, n_1 , and the final window size, n_K , can be adjusted, including setting them both to 0 to tune the mass matrix throughout the tuning phase. Typically, both are set to about 50 or 100.

How the tuning algorithm behaves in the middle tuning windows, and the number and sizes of those windows, depends on the particular settings of the tuning algorithm. There are two more parameters that control this behavior: n_2 , the size of the first middle tuning window; and $\gamma > 0$, which controls how quickly the size of the windows expands. In particular, $n_3 = \lfloor \gamma n_2 \rfloor$, $n_4 = \lfloor \gamma n_3 \rfloor$, and so on, where $\lfloor x \rfloor$ rounds x to the nearest integer from below. The number of tuning windows is not directly controllable; instead the total number of tuning iterations n_{tune} indirectly controls the number of tuning windows. After the initial and final windows, there are $n_{\text{tune}} - n_1 - n_K$ tuning iterations to distribute among the middle tuning windows. The total number of tuning windows, K , is maximized subject to the constraint that the sum of the tuning window sizes be no larger than the total number of tuning iterations; that is,

$$n_1 + n_K + \sum_{k=2}^{K-1} \lfloor \gamma^{k-2} n_2 \rfloor \leq n_{\text{tune}}$$

This procedure does not quite use all available tuning iterations, so any remaining iterations are used in the last middle tuning window, with the result that

$$n_{K-1} = n_{\text{tune}} - n_1 - n_K - \sum_{k=2}^{K-2} \lfloor \gamma^{k-2} n_2 \rfloor$$

For example, if $n_{\text{tune}} = 2,000$, $n_1 = 75$, $n_K = 50$, $n_2 = 25$, and $\gamma = 2$, so that the size of each middle window is double that of the previous middle window, then you have $K = 8$ with the naive tuning window sizes $n_3 = 50$, $n_4 = 100$, $n_5 = 200$, $n_6 = 400$, and $n_7 = 800$. This accounts for 1,700 iterations because

$$75 + 25 + 50 + 100 + 200 + 400 + 800 + 50 = 1,700$$

Then the remaining 300 iterations are used by the final window, so that instead $n_7 = 1,100$.

When the windows are defined, the mass matrix is tuned as follows. Let $\mathbf{M}_k$ denote the mass matrix that is used for sampling in tuning window k . $\mathbf{M}_1$ is the initial mass matrix, and $\mathbf{M}_2 = \mathbf{M}_1$ because no mass matrix tuning is performed in window 1. Then $\mathbf{M}_3$ is the diagonal matrix of inverse sample variances from window 2. Similarly, $\mathbf{M}_4$ is the diagonal matrix of inverse sample variances from window 3, and so on, until $\mathbf{M}_K$ is obtained. Then $\mathbf{M}_K$ is the mass matrix that is used during the final tuning stage, as well as for the rest of posterior sampling.

More formally, let m_{ii}^{k+1} denote the i th diagonal element of $\mathbf{M}_{k+1}$, let t index iterations in the Markov chain, and let θ_i^t denote the t th iteration of element i of $\boldsymbol{\theta}$ in the Markov chain. Then for $k = 2, 4, \dots, K-1$,

$$\frac{1}{m_{ii}^{k+1}} = \frac{1}{n_k} \sum_{t=s_{k-1}+1}^{s_k} \left(\theta_i^t - \bar{\theta}_i^k \right)^2$$

where

$$\bar{\theta}_i^k = \frac{1}{n_k} \sum_{t=s_{k-1}+1}^{s_k} \theta_i^t$$

and $s_k = \sum_{j=1}^k n_j$.

Additionally, expanding window mass matrix tuning can use the previous *two* windows to define the mass matrix for the current window, making it an overlapping expanding-window mass matrix tuning algorithm. In that case, the preceding formula still applies for $k = 2$, but for $k = 3, 4, \dots, K-1$ you have

$$\frac{1}{m_{ii}^{k+1}} = \frac{1}{n_{k-1} + n_k} \sum_{t=s_{k-2}+1}^{s_k} \left(\theta_i^t - \bar{\theta}_i^k \right)^2$$

where

$$\bar{\theta}_i^k = \frac{1}{n_{k-1} + n_k} \sum_{t=s_{k-2}+1}^{s_k} \theta_i^t$$

The expanding-window mass matrix tuning algorithm is quite flexible and can accommodate a wide variety of behaviors through the control of its tuning parameters: the window expansion rate, $\gamma \geq 1$; the initial window size, $n_1 \geq 0$; the final window size, $n_K \geq 0$; the second window size, $n_2 \geq 2$; the choice to use overlapping or nonoverlapping windows; and the total number of tuning iterations, $n_{\text{tune}} \geq 0$. For example, if $n_1 = n_K = 0$, then the mass matrix is tuned throughout the entire tuning phase, and if $\gamma = 1$, then each window is the same size. Despite this flexibility, the performance of NUTS can be dramatically affected by the settings of these parameters. With the exception of n_{tune} , it is generally difficult to choose good values for these parameters, so you should leave them at their default settings if you do not have experience with mass matrix tuning algorithms. In difficult problems where NUTS is not performing well, increasing the value of n_{tune} enables the tuning procedure to obtain better estimates of the posterior variances to use in the mass matrix, and this often improves performance.

Parameter Transformation

Often several parameters of a model are constrained. For example, a standard deviation parameter must be positive, and a correlation parameter must be between -1 and 1 . In these cases, it can be more efficient to transform the constrained parameter to an unconstrained space for sampling, depending on the sampling algorithm that you use. Then, after sampling, you must transform the parameters back to the original, constrained space. There is an additional computational cost associated with transforming and back-transforming, so this technique is typically most advantageous when the posterior mass is concentrated near the boundary. Let the original posterior distribution be denoted by

$$\pi(\theta|\mathbf{y})$$

where $\theta = (\theta_1, \dots, \theta_k)'$ is the parameter vector associated with the model and $\mathbf{y}$ represents the data. Let $\mathbf{u} = T(\theta)$ denote the transformation, where T is an invertible and differentiable function, and $\mathbf{u} = (u_1, \dots, u_k)'$ is the transformed parameter vector. Then the posterior distribution of $\mathbf{u}$ given $\mathbf{y}$ is given by

$$\pi(\mathbf{u}|\mathbf{y}) = \pi(T^{-1}(\mathbf{u})|\mathbf{y})|\mathbf{J}|$$

where $\theta = T^{-1}(\mathbf{u})$ is the inverse transformation and $|\mathbf{J}|$ is the absolute value of the determinant of the Jacobian matrix given by

$$\mathbf{J} = \begin{bmatrix} \frac{\partial \theta_1}{\partial u_1} & \cdots & \frac{\partial \theta_1}{\partial u_k} \\ \vdots & \ddots & \vdots \\ \frac{\partial \theta_k}{\partial u_1} & \cdots & \frac{\partial \theta_k}{\partial u_k} \end{bmatrix}$$

When a subset of the parameters are transformed independently of the other parameters, their Jacobians can be computed separately and their determinants can be multiplied because the Jacobian of transformation of the full parameter vector is block diagonal. In general, if there are m independent transformations, $\mathbf{u}_1 = T_1(\theta_1), \dots, \mathbf{u}_m = T_m(\theta_m)$, where $\theta_1, \dots, \theta_m$ are m distinct subsets of the parameter vector θ , then the Jacobian of $\mathbf{u} = T(\theta) = (T_1(\theta_1), \dots, T_m(\theta_m))$, denoted by $\mathbf{J}$, is given by

$$\mathbf{J} = \begin{bmatrix} \mathbf{J}_1 & & \\ & \ddots & \\ & & \mathbf{J}_m \end{bmatrix}$$

where $\mathbf{J}_i$ is the Jacobian of the transformation T_i and the absolute determinant of $\mathbf{J}$ is given by

$$|\mathbf{J}| = \prod_{i=1}^m |\mathbf{J}_i|$$

In the extreme case in which each parameter is transformed independently of all the other parameters, the determinant of the Jacobian has the form

$$|\mathbf{J}| = \left| \prod_{i=1}^k \frac{\partial \theta_i}{\partial u_i} \right| = \left| \prod_{i=1}^k \frac{\partial T_i^{-1}}{\partial u_i} \right|$$

The gradient of the log posterior is additionally needed for HMC and NUTS:

$$\frac{\partial \log \pi(\mathbf{u}|\mathbf{y})}{\partial \mathbf{u}} = \frac{\partial \log \pi(\boldsymbol{\theta}|\mathbf{y})}{\partial \boldsymbol{\theta}} \frac{\partial \boldsymbol{\theta}}{\partial \mathbf{u}} + \frac{\partial \log |\mathbf{J}|}{\partial \mathbf{u}}$$

In the extreme case where each parameter is transformed independently of all the other parameters, these derivatives can be written as

$$\frac{\partial \log \pi(\mathbf{u}|\mathbf{y})}{\partial u_i} = \frac{\partial \log \pi(\boldsymbol{\theta}|\mathbf{y})}{\partial \theta_i} \frac{\partial \theta_i}{\partial u_i} + \frac{\partial}{\partial u_i} \log \left| \frac{\partial \theta_i}{\partial u_i} \right|$$

The CQLIM and CNTSELECT procedures enable you to transform the parameters before using the random walk Metropolis sampler. Additionally, both procedures automatically transform all parameters as necessary before using the No-U-Turn Sampler. Table 2.11 displays each type of constraint that the parameters can have, as well as the associated transformations, inverse transformations, Jacobians, and derivatives of the log Jacobians.

Table 2.11 Parameter Transformations

Constraint	Transformation	Inverse Transformation	Jacobian	Derivative of Log Jacobian
	$u = T(\theta) =$	$\theta = T^{-1}(u) =$	$\frac{\partial \theta}{\partial u} =$	$\frac{\partial}{\partial u} \log \left \frac{\partial \theta}{\partial u} \right =$
$-\infty < \theta < \infty$	θ	u	1	0
$\min < \theta < \infty$	$\ln(\theta - \min)$	$\min + e^u$	e^u	1
$-\infty < \theta < \max$	$\ln(\max - \theta)$	$\max - e^u$	$-e^u$	1
$\min < \theta < \max$	$\ln \left(\frac{\theta - \min}{\max - \theta} \right)$	$\frac{\min + \max e^u}{1 + e^u}$	$\frac{(\max - \min)e^u}{(e^u + 1)^2}$	$1 - 2 \frac{e^u}{1 + e^u}$

Burn-In, Thinning, and Markov Chain Samples

Burn-in refers to the practice of discarding an initial portion of a Markov chain sample so that the effect of initial values on the posterior inference is minimized. For example, suppose the target distribution is $N(0, 1)$ and the Markov chain was started at the value 10^6 . The chain might quickly travel to regions around 0 in a few iterations. However, including samples around the value 10^6 in the posterior mean calculation can produce substantial bias in the mean estimate. In theory, if the Markov chain is run for an infinite amount of time, the effect of the initial values decreases to zero. In practice, you do not have the luxury of infinite samples. In practice, you assume that after t iterations, the chain has reached its target distribution and you can throw away the early portion and use the good samples for posterior inference. The value of t is the burn-in number.

With some models you might experience poor mixing (or slow convergence) of the Markov chain. This can happen, for example, when parameters are highly correlated with each other. Poor mixing means that the Markov chain slowly traverses the parameter space and the chain has high dependence. High sample autocorrelation can result in biased Monte Carlo standard errors. A common strategy is to *thin* the Markov chain in order to reduce sample autocorrelations. You thin a chain by keeping every k th simulated draw from each sequence. You can safely use a thinned Markov chain for posterior inference as long as the chain converges. It is important to note that thinning a Markov chain can be wasteful because you are throwing away a $\frac{k-1}{k}$ fraction of all the posterior samples generated. MacEachern and Berliner (1994) show that you always get more precise posterior estimates if the entire Markov chain is used. However, other factors, such as computer storage or plotting time, might prevent you from keeping all samples.

To use the CQLIM, CNTSELECT, and SMC procedures, you need to determine the total number of samples to keep ahead of time. This number is not obvious and often depends on the type of inference you want to make. Mean estimates do not require nearly as many samples as small-tail percentile estimates. In most applications, you might find that keeping a few thousand iterations is sufficient for reasonably accurate posterior inference. In all procedures, the relationship between the number of iterations requested, the number of iterations kept, and the amount of thinning is

$$\text{kept} = \left\lceil \frac{\text{requested}}{\text{thinning}} \right\rceil$$

where $\lceil \cdot \rceil$ is the rounding operator.

Assessing Markov Chain Convergence

Simulation-based Bayesian inference requires using simulated draws to summarize the posterior distribution or calculate any relevant quantities of interest. You need to treat the simulation draws with care. There are usually two issues. First, you have to decide whether the Markov chain has reached its stationary, or the desired posterior, distribution. Second, you have to determine the number of iterations to keep after the Markov chain has reached stationarity. Convergence diagnostics help to resolve these issues. Note that many diagnostic tools are designed to verify a necessary but not sufficient condition for convergence. There are no conclusive tests that can tell you when the Markov chain has converged to its stationary distribution. You should proceed with caution. Also, note that you should check the convergence of *all* parameters, and not just those of interest, before proceeding to make any inference. With some models, certain parameters can appear to have very good convergence behavior, but that could be misleading due to the slow convergence of

other parameters. If some of the parameters have bad mixing, you cannot get accurate posterior inference for parameters that appear to have good mixing. See Cowles and Carlin (1996) and Brooks and Roberts (1998) for discussions about convergence diagnostics.

Statistical Diagnostic Tests

The Bayesian procedures include several statistical diagnostic tests that can help you assess Markov chain convergence. For a detailed description of each of the diagnostic tests, see the following subsections. Table 2.12 provides a summary of the diagnostic tests and their interpretations. All these diagnostics are available in the CQLIM, CNTSELECT, and SMC procedures.

Table 2.12 Convergence Diagnostic Tests Available in the Bayesian Procedures

Name	Description	Interpretation of the Test
Geweke	Tests whether the mean estimates have converged by comparing means from the early and latter part of the Markov chain.	Two-sided test based on a z -score statistic. Large absolute z values indicate rejection.
Heidelberger-Welch (stationarity test)	Tests whether the Markov chain is a covariance (or weakly) stationary process. Failure could indicate that a longer Markov chain is needed.	One-sided test based on a Cramér-von Mises statistic. Small p -values indicate rejection.
Heidelberger-Welch (half-width test)	Reports whether the sample size is adequate to meet the required accuracy for the mean estimate. Failure could indicate that a longer Markov chain is needed.	If a relative half-width statistic is greater than a predetermined accuracy measure, this indicates rejection.
Raftery-Lewis	Evaluates the accuracy of the estimated (desired) percentiles by reporting the number of samples needed to reach the desired accuracy of the percentiles. Failure could indicate that a longer Markov chain is needed.	If the total samples needed are fewer than the Markov chain sample, this indicates rejection.
Autocorrelation	Measures dependency among Markov chain samples.	High correlations between long lags indicate poor mixing.
Effective sample size	Relates to autocorrelation; measures mixing of the Markov chain.	Large discrepancy between the effective sample size and the simulation sample size indicates poor mixing.

Geweke Diagnostics

The Geweke test (Geweke 1992) compares values in the early part of the Markov chain to those in the latter part of the chain in order to detect failure of convergence. If the chain has converged, early and later parts of the chain should look similar. The statistic is constructed as follows. Two subsequences of the Markov

chain $\{\theta^t\}$ are taken out, with $\{\theta_1^t : t = 1, \dots, n_1\}$ and $\{\theta_2^t : t = n_a, \dots, n\}$, where $1 < n_1 < n_a < n$. The first subsequence is called the “first window,” and the second sequence is called the “second window.” Let $n_2 = n - n_a + 1$ denote the length of the second window, and define the means of the two windows as

$$\bar{\theta}_1 = \frac{1}{n_1} \sum_{t=1}^{n_1} \theta^t \quad \text{and} \quad \bar{\theta}_2 = \frac{1}{n_2} \sum_{t=n_a}^n \theta^t$$

Let $\hat{s}_1(0)$ and $\hat{s}_2(0)$ denote consistent spectral density estimates at zero frequency (see the section “[Spectral Density Estimate at Zero Frequency](#)” on page 29 for estimation details) for each window. If $n_1 = f_1 n$ and $n_2 = f_2 n$, where the fractions $0 < f_1 < 1$ and $0 < f_2 < 1$ are fixed, $f_1 + f_2 < 1$, and the chain is stationary, then the following statistic converges to a standard normal distribution as $n \rightarrow \infty$:

$$Z_n = \frac{\bar{\theta}_1 - \bar{\theta}_2}{\sqrt{\frac{\hat{s}_1(0)}{n_1} + \frac{\hat{s}_2(0)}{n_2}}}$$

This is a two-sided test, and the p -value is computed as $P(X > |Z_n|)$, where X is a standard normal distribution. A p -value less than α indicates a rejection of the null hypothesis that the first window of the chain and the second window of the chain come from the same distribution. If the null hypothesis is rejected, the Markov chain has not yet converged.

Spectral Density Estimate at Zero Frequency

For one sequence of the Markov chain $\{\theta_t\}$, the relationship between the h -lag covariance sequence of a time series and the spectral density, f , is

$$s_h = \frac{1}{2\pi} \int_{-\pi}^{\pi} \exp(i\omega h) f(\omega) d\omega$$

where i indicates that ωh is the complex argument. Inverting this Fourier integral,

$$f(\omega) = \sum_{h=-\infty}^{\infty} s_h \exp(-i\omega h) = s_0 \left(1 + 2 \sum_{h=1}^{\infty} \rho_h \cos(\omega h) \right)$$

It follows that

$$f(0) = \sigma^2 \left(1 + 2 \sum_{h=1}^{\infty} \rho_h \right)$$

which gives an autocorrelation adjusted estimate of the variance. In this equation, σ^2 is the naive variance estimate of the sequence $\{\theta_t\}$ and ρ_h is the lag h autocorrelation. Due to obvious computational difficulties,

such as calculation of autocorrelation at infinity, you cannot effectively estimate $f(0)$ by using the preceding formula. The usual route is to first obtain the *periodogram* $p(\omega)$ of the sequence, and then estimate $f(0)$ by smoothing the estimated periodogram. The periodogram is defined to be

$$p(\omega) = \frac{1}{n} \left[\left(\sum_{t=1}^n \theta_t \sin(\omega t) \right)^2 + \left(\sum_{t=1}^n \theta_t \cos(\omega t) \right)^2 \right]$$

The procedures use the following way to estimate $\hat{f}(0)$ from p (Heidelberger and Welch 1981). In $p(\omega)$, let $\omega = \omega_k = 2\pi k/n$ and $k = 1, \dots, \lfloor \frac{n}{2} \rfloor$.² A smooth spectral density in the domain of $(0, \pi]$ is obtained by fitting a gamma model with the log link function, using $p(\omega_k)$ as response and $x_1(\omega_k) = \sqrt{3}(4\omega_k/(2\pi) - 1)$ as the only regressor. The predicted value $\hat{f}(0)$ is given by

$$\hat{f}(0) = \exp(\hat{\beta}_0 - \sqrt{3}\hat{\beta}_1)$$

where $\hat{\beta}_0$ and $\hat{\beta}_1$ are the estimates of the intercept and slope parameters, respectively.

Heidelberger-Welch Diagnostics

The Heidelberger-Welch test (Heidelberger and Welch 1981, 1983) consists of two parts: a stationary test and a half-width test. The stationarity test assesses the stationarity of a Markov chain by testing the hypothesis that the chain comes from a covariance stationary process. The half-width test checks whether the Markov chain sample size is adequate to estimate the mean values accurately.

Given $\{\theta^t\}$, set $S_0 = 0$, $S_n = \sum_{t=1}^n \theta^t$, and $\bar{\theta} = (1/n) \sum_{t=1}^n \theta^t$. You can construct the following sequence with s coordinates on values from $\frac{1}{n}, \frac{2}{n}, \dots, 1$:

$$B_n(s) = (S_{[ns]} - [ns]\bar{\theta}) / (n\hat{p}(0))^{1/2}$$

where $[]$ is the rounding operator and $\hat{p}(0)$ is an estimate of the spectral density at zero frequency that uses the second half of the sequence (see the section “[Spectral Density Estimate at Zero Frequency](#)” on page 29 for estimation details). For large n , B_n converges in distribution to a Brownian bridge (Billingsley 1986). So you can construct a test statistic by using B_n . The statistic that these procedures use is the Cramér–von Mises statistic;³ that is, $\int_0^1 B_n(s)^2 ds = \text{CVM}(B_n)$. As $n \rightarrow \infty$, the statistic converges in distribution to a standard Cramér–von Mises distribution. The integral $\int_0^1 B_n(s)^2 ds$ is numerically approximated using Simpson’s rule.

Let $y_i = B_n(s)^2$, where $s = 0, \frac{1}{n}, \dots, \frac{n-1}{n}, 1$ and $i = ns = 0, 1, \dots, n$. If n is even, let $m = n/2$; otherwise, let $m = (n-1)/2$. The Simpson’s approximation to the integral is

$$\int_0^1 B_n(s)^2 ds \approx \frac{1}{3n} [y_0 + 4(y_1 + \dots + y_{2m-1}) + 2(y_2 + \dots + y_{2m-2}) + y_{2m}]$$

²This is equivalent to the fast Fourier transformation of the original time series θ_t .

³ The von Mises distribution was first introduced by von Mises (1918). The density function is $\pi(\theta|\mu\kappa) \sim M(\mu, \kappa) = [2\pi I_0(\kappa)]^{-1} \exp(\kappa \cos(\theta - \mu))$ ($0 \leq \theta \leq 2\pi$), where the function $I_0(\kappa)$ is the modified Bessel function of the first kind and order zero, defined by $I_0(\kappa) = (2\pi)^{-1} \int_0^{2\pi} \exp(\kappa \cos(\theta - \mu)) d\theta$.

Note that Simpson's rule requires an even number of intervals. When n is odd, y_n is set to 0 and the value does not contribute to the approximation.

This is a one-sided test, and the p -value is computed as $P(X > \text{CVM}(B_n))$, where X has a standard Cramér–von Mises distribution. A p -value less than α indicates rejection of the null hypothesis that the chain is stationary. This test can be performed repeatedly on the same chain, and it helps you identify a time t when the chain has reached stationarity. The whole chain, $\{\theta^t\}$, is first used to construct the Cramér–von Mises statistic. If it passes the test, you can conclude that the entire chain is stationary. If it fails the test, you drop the initial 10% of the chain and redo the test by using the remaining 90%. This process is repeated until either a time t is selected or it reaches a point where there are not enough data remaining to construct a confidence interval (the cutoff proportion is set to 50%).

The part of the chain that is deemed stationary is put through a half-width test, which reports whether the sample size is adequate to meet certain accuracy requirements for the mean estimates. Running the simulation less than this length of time would not meet the requirement, whereas running it longer would not provide any additional information that is needed. The statistic that is calculated here is the *relative half-width* (RHW) of the confidence interval. The RHW for a confidence interval of level $1 - \alpha$ is

$$\text{RHW} = \frac{z_{(1-\alpha/2)} \cdot (\hat{s}_n/n)^{1/2}}{\hat{\theta}}$$

where $z_{(1-\alpha/2)}$ is the z -score of the $100(1 - \alpha/2)$ th percentile (for example, $z_{(1-\alpha/2)} = 1.96$ if $\alpha = 0.05$), $\hat{s}_n$ is the variance of the chain estimated using the spectral density method (see the explanation in the section “Spectral Density Estimate at Zero Frequency” on page 29), n is the length, and $\hat{\theta}$ is the estimated mean. The RHW quantifies accuracy of the $1 - \alpha$ level confidence interval of the mean estimate by measuring the ratio between the sample standard error of the mean and the mean itself. The test assumes that you can stop the Markov chain if the variability of the mean stabilizes with respect to the mean—in other words, if the RHW is small enough. An implicit assumption is that large means are often accompanied by large variances. If this assumption is not met, then this test can produce false rejections (such as a small mean around 0 and large standard deviation) or false acceptance (such as a very large mean with relative small variance). As with any other convergence diagnostics, you might want to exercise caution in interpreting the results.

To perform the stationarity test, you need to select an α level (the default is 0.05). To perform the half-width test, you need to select another α level (again, the default is 0.05) and a predetermined tolerance value ϵ (the default is 0.1). If the calculated RHW is greater than ϵ , you conclude that there are not enough data to accurately estimate the mean with $1 - \alpha$ confidence under a tolerance of ϵ .

Raftery-Lewis Diagnostics

If your interest lies in posterior percentiles, you want a diagnostic test that evaluates the accuracy of the estimated percentiles. The Raftery-Lewis test (Raftery and Lewis 1992, 1995) is designed for this purpose. The Raftery-Lewis test evaluates the accuracy of a quantile estimate $\hat{\theta}_q$ of order $q \in (0, 1)$. In particular, it determines the number of MCMC iterations, M , that need to be discarded (burn-ins) and the number of iterations that are needed, N , in order to achieve a desired level of precision in the estimate $\hat{\theta}_q$. Details follow. Notation and deductions here closely resemble those in Raftery and Lewis (1995).

The quantile θ_q is defined such that $P(\theta \leq \theta_q | \mathbf{y}) = q$, where q can be an arbitrary cumulative probability, such as 0.025. This θ_q can be empirically estimated by finding the $100nq$ th number of the sorted $\{\theta^t\}$. Let $\hat{\theta}_q$ denote the estimand, which corresponds to an estimated probability $P(\theta \leq \hat{\theta}_q) = \hat{P}_q$. Because the simulated

posterior distribution converges to the true distribution as the simulation sample size grows, $\hat{\theta}_q$ can achieve any degree of accuracy if the simulator is run for a very long time. However, running a simulation for too long can be wasteful. Alternatively, you can use coverage probability to measure accuracy and stop the chain when a certain accuracy is reached.

A stopping criterion is reached when the estimated probability is within $\pm r$ of the true cumulative probability q , with probability s , such as $P(\hat{P}_q \in (q - r, q + r)) = s$. For example, suppose you want the coverage probability s to be 0.95 and the amount of tolerance r to be 0.005. This corresponds to requiring that the estimate of the cumulative distribution function of the 2.5th percentile be estimated to within ± 0.5 percentage points with probability 0.95. In order to perform the diagnostic, a value ϵ must be chosen for the tolerance level of a stationary test, described in the following paragraphs. For example, $\epsilon = 0.001$.

The Raftery-Lewis diagnostic test finds the number of iterations, M , that need to be discarded (burn-ins) and the number of iterations that are needed, N , in order to achieve a desired precision. Given a predefined cumulative probability q , these procedures first find $\hat{\theta}_q$, and then they construct a binary 0 – 1 process $\{Z_t\}$ by setting $Z_t = 1$ if $\theta^t \leq \hat{\theta}_q$ and 0 otherwise for all t . The sequence $\{Z_t\}$ is itself not a Markov chain, but you can construct a subsequence of $\{Z_t\}$ that is approximately Markovian if it is sufficiently k -thinned. When k becomes reasonably large, $\{Z_t^{(k)}\}$ starts to behave like a Markov chain.

Next, the procedures find this thinning parameter k . The number k is estimated by comparing the Bayesian information criterion (BIC) between two Markov models: a first-order and a second-order Markov model. A j th-order Markov model is one in which the current value of $\{Z_t^{(k)}\}$ depends on the previous j values. For example, in a second-order Markov model,

$$\begin{aligned} P(Z_t^{(k)} = z_t | Z_{t-1}^{(k)} = z_{t-1}, Z_{t-2}^{(k)} = z_{t-2}, \dots, Z_0^{(k)} = z_0) \\ = P(Z_t^{(k)} = z_t | Z_{t-1}^{(k)} = z_{t-1}, Z_{t-2}^{(k)} = z_{t-2}) \end{aligned}$$

where $z_i = \{0, 1\}, i = 0, \dots, t$. Given $\{Z_t^{(k)}\}$, you can construct two transition count matrices for a second-order Markov model:

$$\begin{array}{cc|cc} & & z_t = 0 & & z_t = 1 \\ & & z_{t-1} = 0 & z_{t-1} = 1 & z_{t-1} = 0 & z_{t-1} = 1 \\ z_{t-2} = 0 & w_{000} & w_{010} & z_{t-2} = 0 & w_{001} & w_{011} \\ z_{t-2} = 1 & w_{100} & w_{110} & z_{t-2} = 1 & w_{101} & w_{111} \end{array}$$

For each k , the procedures calculate the BIC that compares the two Markov models. The BIC is based on a likelihood ratio test statistic that is defined as

$$G_k^2 = 2 \sum_{i=0}^1 \sum_{j=0}^1 \sum_{l=0}^1 w_{ijl} \log \frac{w_{ijl}}{\hat{w}_{ijl}}$$

where $\hat{w}_{ijl}$ is the expected cell count of w_{ijl} under the null model, the first-order Markov model, where the assumption $(Z_t^{(k)} \perp Z_{t-2}^{(k)}) | Z_{t-1}^{(k)}$ holds. The formula for the expected cell count is

$$\hat{w}_{ijl} = \frac{\sum_i w_{ijl} \cdot \sum_l w_{ijl}}{\sum_i \sum_l w_{ijl}}$$

The BIC is $G_k^2 - 2 \log(n_k - 2)$, where n_k is the k -thinned sample size (every k th sample, starting with the first), with the last two data points discarded because of the construction of the second-order Markov model. The thinning parameter k is the smallest k for which the BIC is negative. When k is found, you can estimate a transition probability matrix between state 0 and state 1 for $\{Z_t^{(k)}\}$:

$$Q = \begin{pmatrix} 1 - \alpha & \alpha \\ \beta & 1 - \beta \end{pmatrix}$$

Because $\{Z_t^{(k)}\}$ is a Markov chain, its equilibrium distribution exists and is estimated by

$$\pi = (\pi_0, \pi_1) = \frac{(\beta, \alpha)}{\alpha + \beta}$$

where $\pi_0 = P(\theta \leq \theta_q | \mathbf{y})$ and $\pi_1 = 1 - \pi_0$. The goal is to find an iteration number m such that after m steps, the estimated transition probability $P(Z_m^{(k)} = i | Z_0^{(k)} = j)$ is within ϵ of equilibrium π_i for $i, j = 0, 1$. Let $e_0 = (1, 0)$ and $e_1 = 1 - e_0$. The estimated transition probability after step m is

$$P(Z_m^{(k)} = i | Z_0^{(k)} = j) = e_j \left[\begin{pmatrix} \pi_0 & \pi_1 \\ \pi_0 & \pi_1 \end{pmatrix} + \frac{(1 - \alpha - \beta)^m}{\alpha + \beta} \begin{pmatrix} \alpha & -\alpha \\ -\beta & \beta \end{pmatrix} \right] e_j'$$

which holds when

$$m = \frac{\log \left(\frac{(\alpha + \beta)\epsilon}{\max(\alpha, \beta)} \right)}{\log(1 - \alpha - \beta)}$$

assuming $1 - \alpha - \beta > 0$.

Therefore, by time m , $\{Z_t^{(k)}\}$ is sufficiently close to its equilibrium distribution, and you know that a total size of $M = mk$ should be discarded as the burn-in.

Next, the procedures estimate N , the number of simulations that are needed in order to achieve the desired accuracy in percentile estimation. The estimate of $P(\theta \leq \theta_q | \mathbf{y})$ is $\bar{Z}_n^{(k)} = \frac{1}{n} \sum_{t=1}^n Z_t^{(k)}$. For large n , $\bar{Z}_n^{(k)}$ is normally distributed with mean q , the true cumulative probability, and variance

$$\frac{1}{n} \frac{(2 - \alpha - \beta)\alpha\beta}{(\alpha + \beta)^3}$$

$P(q - r \leq \bar{Z}_n^{(k)} \leq q + r) = s$ is satisfied if

$$n = \frac{(2 - \alpha - \beta)\alpha\beta}{(\alpha + \beta)^3} \left\{ \frac{\Phi^{-1}\left(\frac{s+1}{2}\right)}{r} \right\}^2$$

Therefore, $N = nk$.

By using similar reasoning, the procedures first calculate the minimal number of iterations that are needed in order to achieve the desired accuracy, assuming that the samples are independent:

$$N_{\min} = \left\{ \Phi^{-1}\left(\frac{s+1}{2}\right) \right\}^2 \frac{q(1-q)}{r^2}$$

If $\{\theta^t\}$ does not have that required sample size, the Raftery-Lewis test is not performed. If you still want to perform the test, increase the number of Markov chain iterations.

The ratio $N/N_{\min}$ is sometimes referred to as the *dependence factor*. It measures deviation from posterior sample independence: the closer it is to 1, the less correlated the samples are. There are a few things to keep in mind when you use this test. This diagnostic tool is specifically designed for the percentile of interest and does not provide information about convergence of the chain as a whole (Brooks and Roberts 1999). In addition, the test can be very sensitive to small changes. Both N and $N_{\min}$ are inversely proportional to r^2 , so you can expect to see large variations in these numbers with small changes to input variables, such as the desired coverage probability or the cumulative probability of interest. Finally, the time until convergence for a parameter can differ substantially for different cumulative probabilities.

Autocorrelations

The sample autocorrelation of lag h for a parameter θ is defined in terms of the sample autocovariance function:

$$\hat{\rho}_h(\theta) = \frac{\hat{\gamma}_h(\theta)}{\hat{\gamma}_0(\theta)}, \quad |h| < n$$

The sample autocovariance function of lag h of θ is defined by

$$\hat{\gamma}_h(\theta) = \frac{1}{n-h} \sum_{t=1}^{n-h} (\theta^{t+h} - \bar{\theta})(\theta^t - \bar{\theta}), \quad 0 \leq h < n$$

Effective Sample Size

You can use autocorrelation and trace plots to examine the mixing of a Markov chain. A closely related measure of mixing is the effective sample size (ESS) (Kass et al. 1998). ESS can be interpreted as the equivalent number of independent draws from the posterior distribution that the Markov chain represents.

ESS is defined as

$$\text{ESS} = \frac{n}{\tau} = \frac{n}{1 + 2 \sum_{k=1}^{\infty} \rho_k(\theta)}$$

where n is the total sample size and $\rho_k(\theta)$ is the autocorrelation of lag k for θ . The quantity τ is referred to as the autocorrelation time. To estimate τ , the Bayesian procedures first find a cutoff point k after which the autocorrelations are very close to zero, and then sum all the ρ_k up to that point. The cutoff point k is such that $|\rho_k| < \min\{0.01, 2s_k\}$, where s_k is the estimated standard deviation:

$$s_k = \sqrt{\left(\frac{1}{n} \left(1 + 2 \sum_{j=1}^{k-1} \hat{\rho}_j^2(\theta) \right) \right)}$$

ESS and τ are inversely proportional to each other, and low ESS or high τ indicates bad mixing of the Markov chain.

ESS is costly to compute when the Markov chain is highly autocorrelated because it requires so many autocorrelation lags to be computed first. To remedy this problem, you can specify the cutoff point to be no larger than some maximum lag. In the case where more than the maximum number of lags would be required, this reduces computational cost but results in poor-quality estimates of ESS and τ . However, when the maximum lag is set high enough, this problem occurs only when the Markov chain is mixing very poorly, which is precisely the issue that ESS and τ are meant to diagnose.

Summary Statistics

Let θ be a p -dimensional parameter vector of interest: $\theta = \{\theta_1, \dots, \theta_p\}$. For each $i \in \{1, \dots, p\}$, there are n observations: $\theta_i = \{\theta_i^t, t = 1, \dots, n\}$.

Mean

The posterior mean is calculated by using the following formula:

$$E(\theta_i | \mathbf{y}) \approx \bar{\theta}_i = \frac{1}{n} \sum_{t=1}^n \theta_i^t, \text{ for } i = 1, \dots, p$$

Standard Deviation

Sample standard deviation is computed as the square root of the sample variance, which is calculated by using the following formula:

$$\text{Var}(\theta_i | \mathbf{y}) \approx s_i^2 = \frac{1}{n-1} \sum_{t=1}^n (\theta_i^t - \bar{\theta}_i)^2$$

Standard Error of the Mean Estimate

Suppose that you have n iid samples, the mean estimate is $\bar{\theta}_i$, and the sample standard deviation is s_i . The standard error of the estimate is $\hat{\sigma}_i / \sqrt{n}$. However, positive autocorrelation (see the section “[Autocorrelations](#)” on page 34 for a definition) in the MCMC samples makes this an underestimate. To account for the autocorrelation, the Bayesian procedures correct the standard error by using effective sample size (see the section “[Effective Sample Size](#)” on page 34).

Given an effective sample size of m , the standard error for $\bar{\theta}_i$ is $\hat{\sigma}_i / \sqrt{m}$. The following formula for the variance of $\bar{\theta}_i$ is equivalent:

$$\widehat{\text{Var}}(\bar{\theta}_i) = \frac{1 + 2 \sum_{k=1}^{\infty} \rho_k(\theta_i)}{n} \cdot \frac{\sum_{t=1}^n (\theta_i^t - \bar{\theta}_i)^2}{(n-1)}$$

The standard error of the mean is also known as the Monte Carlo standard error (MCSE). The MCSE provides a measurement of the accuracy of the posterior estimates, and small values do not necessarily indicate that you have recovered the true posterior mean.

Percentiles

Sample percentiles are calculated using the following steps. Let τ denote a percentile; let $p = \frac{\tau}{100}$; let the τ th percentile of θ_i be θ_i^p ; and let $\theta_{i(t)}$ for $t = 1, 2, \dots, n$ denote the posterior sample of θ_i , sorted so that $\theta_{i(t)} \leq \theta_{i(t+1)}$ for all t . Next define $np = j + g$, where j is the integer part of np and g is the fractional part. Then the τ th percentile of the posterior distribution of θ_i is calculated as

$$\theta_i^p = \begin{cases} \frac{1}{2} (\theta_{i(j)} + \theta_{i(j+1)}) & \text{if } g = 0 \\ \theta_{i(j+1)} & \text{if } g > 0 \end{cases}$$

Correlation

Correlation between θ_i and θ_j is calculated as

$$r_{ij} = \frac{\sum_{t=1}^n (\theta_i^t - \bar{\theta}_i) (\theta_j^t - \bar{\theta}_j)}{\sqrt{\sum_t (\theta_i^t - \bar{\theta}_i)^2 \sum_t (\theta_j^t - \bar{\theta}_j)^2}}$$

Covariance

Covariance between θ_i and θ_j is calculated as

$$s_{ij} = \sum_{t=1}^n (\theta_i^t - \bar{\theta}_i) (\theta_j^t - \bar{\theta}_j) / (n-1)$$

Equal-Tail Credible Interval

Let $\Pi(\theta_i | \mathbf{y})$ denote the marginal posterior cumulative distribution function of θ_i . A 100 $(1 - \alpha)$ % Bayesian equal-tail credible interval for θ_i is $(\theta_i^{\alpha/2}, \theta_i^{1-\alpha/2})$, where $\Pi(\theta_i^{\alpha/2} | \mathbf{y}) = \frac{\alpha}{2}$ and $\Pi(\theta_i^{1-\alpha/2} | \mathbf{y}) = 1 - \frac{\alpha}{2}$. The interval is obtained using the empirical $\frac{\alpha}{2}$ th and $(1 - \frac{\alpha}{2})$ th percentiles of $\{\theta_i^t\}$.

Highest Posterior Density (HPD) Interval

For a definition of an HPD interval, see the section “[Interval Estimation](#)” on page 10. SAS Econometrics procedures use the Chen-Shao algorithm (Chen and Shao 1999; Chen, Shao, and Ibrahim 2000) to estimate an empirical HPD interval of θ_i :

1. Sort $\{\theta_i^t\}$ to obtain the ordered values:

$$\theta_{i(1)} \leq \theta_{i(2)} \leq \dots \leq \theta_{i(n)}$$

2. Compute the 100 $(1 - \alpha)$ % credible intervals:

$$R_j(n) = (\theta_{i(j)}, \theta_{i(j + [(1-\alpha)n])})$$

for $j = 1, 2, \dots, n - [(1 - \alpha)n]$.

3. The 100 $(1 - \alpha)$ % HPD interval, denoted by $R_{j^*}(n)$, is the one with the smallest interval width among all credible intervals.

Using Multiple Chains

An effective strategy to check for convergence is to run multiple chains and check whether they yield similar results. Then the chains must be combined appropriately to compute both multichain posterior summary statistics and multichain MCMC diagnostics. For multichain posterior summary statistics such as the posterior mean, posterior quantiles, posterior intervals, or the posterior covariance and correlation matrices, the chains can be combined into one long chain, and then the statistics can be computed as if there were only one chain. To compute the MCSE of multichain estimates, or to compute multichain convergence diagnostics, you must take more care to account for the different autocorrelation structures in each of the chains.

Multichain Standard Error of the Mean Estimate

Suppose there are m chains, each of n iterations. Then each chain yields an estimate of the posterior mean of the parameter θ of the form

$$\bar{\theta}_j = \frac{1}{n} \sum_{t=1}^n \theta^{jt}$$

where $j = 1, 2, \dots, m$ index chains. Based on the central limit theorem, these estimates are independent and have the following asymptotic normal distributions:

$$\bar{\theta}_j \sim N(\mu, \sigma^2 / \text{ESS}_j)$$

where $\mu = E(\theta|y)$ is the true posterior mean, $\sigma^2 = E((\theta - \mu)^2|y)$ is the true posterior variance, and ESS_j is the effective sample size of θ in the j th chain.

The multichain estimate of the posterior mean is the mean of all the iterations over all chains, which is equivalent to taking the mean of single-chain posterior mean estimates. Then the asymptotic distribution of the multichain estimate of the posterior mean is

$$\bar{\theta} = \frac{1}{m} \sum_{j=1}^m \bar{\theta}_j \sim N \left(\mu, \frac{\sigma^2}{m^2} \sum_{j=1}^m \frac{1}{ESS_j} \right)$$

Then σ^2 is estimated using the multichain estimate of the posterior variance, denoted by $\hat{\sigma}^2$, and obtained by computing the sample variance, using all chains as one large sample. Estimates of the effective sample sizes are obtained via $ESS_j = n/\tau_j$, where τ_j is the estimated autocorrelation time for θ in the j th chain. This yields

$$\widehat{\text{Var}}(\bar{\theta}) = \frac{\hat{\sigma}^2}{nm} \frac{\sum_{j=1}^m \tau_j}{m}$$

The multichain MCSE is the square root of this value.

Multichain Effective Sample Size

From the preceding formula for multichain MCSE, multichain estimates of effective sample size and autocorrelation time naturally arise. The multichain estimate of autocorrelation time is simply the mean of the single-chain autocorrelation times:

$$\tau = \frac{1}{m} \sum_{j=1}^m \tau_j$$

Given τ , the multichain estimate of ESS is

$$ESS = \frac{nm}{\tau}$$

Multichain Autocorrelations

The multichain estimate of autocorrelation time can be equivalently constructed by first computing the mean autocorrelations for each lag, then computing autocorrelation time using the mean autocorrelations. So the multichain estimate of the lag- h autocorrelation is the mean autocorrelation for that lag, given by

$$\rho_h = \frac{1}{m} \sum_{j=1}^m \rho_{jh}$$

where ρ_{jh} is the lag- h autocorrelation from the j th chain.

Other Diagnostics

The Geweke, Heidelberger-Welch, and Raftery-Lewis diagnostics are solely single-chain diagnostics and cannot be constructed for multiple chains. They can be used with multiple chains by constructing them for each chain and then by checking whether all chains pass the diagnostic. For example, the Geweke diagnostic and the stationarity test of the Heidelberger-Welch diagnostic can both detect whether any of the chains have not yet converged. However, the half-width test of the Heidelberger-Welch diagnostic and the Raftery-Lewis diagnostic both assume that you will use only a single chain to do posterior inference. This means that these tests will sometimes tell you that you need longer chains than necessary to achieve adequate precision in estimating posterior quantities.

A Bayesian Reading List

This section lists a number of Bayesian textbooks of varying levels.

Introductory Books

- Berry, D. A. (1996). *Statistics: A Bayesian Perspective*. Belmont, CA: Duxbury Press.
- Bolstad, W. M. (2016). *Introduction to Bayesian Statistics*. 3rd ed. Hoboken, NJ: John Wiley & Sons.

Overview

The chapter describes the use of packages in the TSMODEL procedure. It defines the main concepts of packages and describes the steps for using packages in the TSMODEL procedure, the package syntax conventions and terminology, and the structural organization of each package’s chapter.

NOTE: When you license SAS Visual Forecasting, you also have access to SAS/ETS software and SAS Forecast Server Procedures. For more information about SAS/ETS procedures, see *SAS/ETS User’s Guide*. For more information about SAS Forecast Server Procedures, see *SAS Forecast Server Procedures: User’s Guide*.

What Is a Package?

A package is a set of related specialized objects and functions that tackles a unique facet of the time series analysis problem. You can use these specialized objects and functions when you write your custom SAS code in order to gain access both to cutting-edge data analysis tools and to utilities that are designed to significantly speed up code development and improve the quality of the resulting code.

Table 3.1 shows the packages that you can use with the TSMODEL procedure. Each package has a unique abbreviation that contains up to five alphabetic characters.

Table 3.1 Packages for the TSMODEL Procedure

Package Name	Abbreviation	Description
Automatic time series analysis and forecasting	ATSM	Tools for automatic modeling and forecasting of time series using various model families such as exponential smoothing (ESM), ARIMA, intermittent demand (IDM), and unobserved component models (UCM)
External Languages	EXTLANG	Tools for enabling the seamless integration of external language programs into SAS environments
Time series motif discovery	MOTIF	Tools for the discovery of frequent patterns or repeated subsequences in time series
Multivariate singular spectrum analysis	MSSA	Tools for decomposing a multivariate time series into additive components and categorizing those components based on the magnitudes of their contributions
Simple forecast service	SFS	Tools for automatic forecasting of time series with a simple-to-use interface and using only ARIMA models
Singular spectrum analysis	SSA	Tools for decomposing a time series into additive components and categorizing those components based on the magnitudes of their contributions
Subspace tracking	SST	Tools for tracking the principal subspace of multiple time series
Time filters	TIMFIL	Tools for filtering and aggregation of time series
Time frequency analysis	TFA	Tools for efficient analysis of time series in both time and frequency domains
Time series analysis	TSA	Tools for efficient statistical analysis of time series (transformations, decompositions, statistical tests for intermittency, seasonality, stationarity, and forecast bias, and so on)
Time series dimension reduction	TDR	Tools for reducing the dimensionality of time series

Table 3.1 *continued*

Package Name	Abbreviation	Description
Time series distance measure	TSD	Tools for measuring the distance between two time series or among sequences in temporal data
Time series model	TSM	Tools for efficient time series modeling and forecasting
Utility	UTL	Tools for performing basic statistical computations on pairs of actual and predicted time series

What Are Objects, Classes, Instances, Functions, and Methods?

This section describes the computer programming terminology that is used in the documentation of packages for the TSMODEL procedure.

What Are Objects?

A programming object, a fundamental concept in object-oriented programming (OO) and analogous to an object found in nature, is the description of the state and behavior of a system. For example, a dog is a real-world object that has both a state (name, age, weight, fur color, tail length, running speed, number of teeth, friendliness level, and so on) and behavior (running, biting, eating, hunting, wagging its tail, whining, sleeping, tearing the sofa, and so on). A programming object is similar to a real-world object, but it stores its state as internal variables called fields and communicates its behavior to other objects via a set of functions called methods.

Many of the objects in the TSMODEL procedure packages are collector objects that are specifically designed to postprocess the output of other objects and then store the results in an output table. This postprocessing and storing the results can help accelerate your development process. These objects are called collectors because they “gather” the results of other objects and store them for future reference.

Conversely, some other objects are specifically designed to retrieve the data that have been stored in an output table by collectors and make those data available to your custom SAS code. These objects are called repeater objects.

What Are Classes?

A class is a programming recipe for creating objects. Whereas real objects can be described by an unlimited number of features, a class uses a limited number of features to describe as faithfully as possible both the state and behavior of an object inside a computer program. The size and complexity of the feature set that a class uses (that is, how complex the recipe for the object is) depends on the requirements of each application. A class uses fields of varying data types to represent the features that describe the state of an object. Similarly, a class provides a set of methods that enables external objects to query and even modify the object's behavior. Furthermore, a class also generally provides the recipe for a constructor, which is a special method that assigns an initial state to the class fields.

The words “class” and “object” are sometimes used interchangeably because a class is the representation of an object within the constraints of a programming language.

What Are Instances?

An instance of a class is a unique replica of a class that represents an object inside a computer program. A computer program creates instances of a class by allocating a block of memory and using different portions of that block to represent the different fields and methods that are described in the recipe given by the class. A computer program can create multiple unique instances of the same class in memory to represent many independent objects.

What Are Functions?

A function, a fundamental concept in computer programming, is a named block of instructions that performs a specific task. Functions allow programs to be modularized into reusable blocks of code that are written once and can then be invoked many times. In addition, modularization makes a program more readable and enables developers to work simultaneously on different portions of the same program.

What Are Methods?

A method is similar to a function, but it belongs to a specific class. In a computer program, all instances of a class contain the same methods. However, the methods of each instance can access only the instance's own internal variables. Functions can interact with instances of a class by invoking its methods.

How Do You Use Packages?

There are two steps involved in using packages in the TSMODEL procedure. First, you specify in the REQUIRE statement the packages that you want to use in your SAS code. Second, you declare instances of package objects in your SAS code by using a DECLARE OBJECT statement for each instance. The following sections further elaborate on these steps.

The REQUIRE Statement

The REQUIRE statement in the TSMODEL procedure enables your custom SAS code to access the objects and functions in the packages that are specified in the statement. You can use specify multiple packages in a single REQUIRE statement, as follows:

```
REQUIRE package-1 < package-2 ... package-n > ;
```

You can selectively identify which objects within a package you intend to use, as shown in the following statement:

```
REQUIRE package (class-1 ... class-n) ;
```

In contrast to objects, the functions offered by a package are always available when a package is registered via the REQUIRE statement; they do not have to be individually specified.

The REQUIRE statement does not automatically create any instances of the objects in the packages that you specify. For more information about the REQUIRE statement, see the Chapter 16, “TSMODEL Procedure” (*SAS Visual Forecasting: Forecasting Procedures*).

The DECLARE OBJECT Statement

You use the DECLARE OBJECT statement in your custom SAS code to create one or more unique instances of package objects. Instances of the same object are completely independent from each other, and there is no limit on how many instances of an object you can create in your program. You can access package functions by simply invoking them directly from your custom SAS code, but you must declare instances of package objects in order to use them in your custom SAS code. You interact with instances of objects by invoking their methods, as is illustrated in the following statements:

```
DECLARE OBJECT name-1 (class) ;
```

```
DECLARE OBJECT name-2 (class) ;
```

```
rc1=name1.SomeMethod (Argument-1 ... Argument-n) ;
```

```
rc2=name2.SomeMethod (Argument-1 ... Argument-n) ;
```

These statements declare two unique instances of the *class* object: *name1* and *name2*. You can interact with these two instances independently by invoking their *SomeMethod* method and passing in the required arguments. Method calls always return a numeric status code (*rc*) to indicate successful or failure. By convention, the objects in the TSMODEL procedure packages return a negative number to indicate that a computational failure has occurred.

Chapter Organization

This book is organized as follows.

This chapter provides an overview that describes what packages for the TSMODEL procedure are and how they are used.

The remaining chapters describe the various packages that are available for the TSMODEL procedure. Each of these chapters is organized as follows:

- The “Overview” section describes the broad purpose of the package; it describes which specific facet of the time series analysis problem the package is designed to tackle. It also provides a table that lists all the objects and functions that are offered by the package along with a brief description of each object’s functionalities. You can use the contents of this table to quickly locate an object that offers the functionalities you need. For packages that contain objects that interact with each other to perform larger and more complex tasks, a data flow diagram is also provided in this section to succinctly describe the interactions between the various objects via their methods. The direction of the arrows in this diagram indicates how the output of object methods feeds into other object methods. This section also describes the status codes that can be returned by an object methods and functions in the packages.
- A section for each object follows the “Overview” section. Sections for objects have the following structure:
 - The “Object Summary” section is divided into three parts: “Synopsis,” “Data Flow Diagram,” and “Methods.” Each object that is offered by a package has its own “Object Summary” section, which starts with a detailed description of the functionality of the object. Read this section if you want to understand more about the inner workings of an object (for example, to find out mathematical techniques that an object uses internally). This section also includes a table that summarizes all the available object methods along with a brief description of their functionalities. Refer to this table to quickly determine how to control the behavior of an object. You can also search for the methods that are prefixed with “Set” and “Get.” In addition, if the object is a collector, this section provides a table that describes the corresponding table schema that the object generates. The table schema description includes the name, SAS data type, and a brief description of each table column.
 - The “Synopsis” section shows how you can declare an instance of the object in your custom SAS code. This section describes the correct sequence of method calls (when a particular sequence is required) and indicates which method arguments are optional or mandatory. For example, for the FORENG object in the ATSM package, you provide forecast data to the FORENG object via its Initialize method, optionally set the forecast lead via the SetOption method, then run the forecast via its Run method, and optionally retrieve a forecast series via the GetForecast method. The “Synopsis” section also optionally offers a data flow diagram of the object that depicts the flow of data into and out of the object via its methods and the relevant data types that are required as arguments by each method. This diagram provides you with a visual overview of how to interact with the object from your program.
 - The “Methods” section provides a detailed description of the object’s methods. A subsection for each method includes its functionality and arguments. Method arguments are divided into either

input or output arguments. Input arguments are not modified by a method internally. Output arguments can be modified by a method internally. The size and value of an output argument after the execution of a method might differ from its original size and value before the method call, but the data type always remains the same. The description of each argument also lists the SAS data types that are acceptable for that argument. Each method argument can accept one or more SAS data types.

- The “Examples” section follows the detailed description of all the package’s objects. This section includes various examples that depict how the various objects provided by the package interact with each other and how they interact with objects in other packages to solve problems. These examples generally use almost all methods in each object and can provide a good starting point for your own custom implementations.
- The “References” section contains references for the methodology and for examples of the procedure.

Syntax Conventions

This section describes the common terminology and design patterns that are used by all packages that can be used with the TSMODEL procedure.

Object Names

Names of collector objects have the prefix “OUT” followed by a descriptive object name. For example, the OUTFREQ collector object is designed to store the results of an instance of the FREQ object in the TSA package. Similarly, the OUTEST object is designed to store the time series model parameter estimates that are computed by an instance of the FORENG object in the ATSM package.

Similarly, names of repeater objects have the prefix “IN” followed by a descriptive object name. For example, the INDIAG object is used to read in the set of diagnostic control specifications that were previously stored into a table by an instance of the OUTDIAG collector object in the ATSM package.

Object Method Names

Many of the objects in the TSMODEL procedure packages allow their behaviors to be controlled via the specification of options. For example, the FORENG object in the ATSM package provides automatic time series forecasting capabilities and enables you to specify the lead time, forecast horizon, and confidence level size of the computed forecast confidence limits, among many other options that affect the forecast. Names of object methods that are designed specifically for setting options have the prefix “Set” followed by the option name, as in the following example:

```
DECLARE OBJECT s (SFS) ;
```

```
rc=s.SetY (y) ;
```

In addition, various objects offer a single overarching method called “SetOption” that is used to set all object properties, with the exception of the input time series data. To quickly determine how to control the behavior of objects, you can search for the description of an overarching “SetOption” method in the documentation of the objects that you plan to use in your custom SAS code. Similarly, names of object methods that are designed specifically to enable you to retrieve both data and properties from objects have the prefix “Get” followed by a descriptive name. For example, the “GetForecast” method in the FORENG object enables you to retrieve various forecast series that are computed by the object and include them in your custom SAS code for further processing.

Return Codes

All object methods and functions offered by the TSMODEL procedure packages return a status code upon their execution. Negative status codes are used to indicate the occurrence of computational failures. Positive return codes, including 0, are customized to the needs of individual objects and functions. Generally, a status code of 0 indicates unconditional success, and a status code greater than 0 indicates conditional success.

Introduction to Shared Concepts

SAS Econometrics procedures run on SAS Viya. One component of SAS Viya is SAS Cloud Analytic Services (CAS), which is the analytic server and associated cloud services. The following subsections describe how to set up and use CAS sessions.

The section “[Syntax Common to SAS Econometrics Procedures](#)” on page 56 describes the common syntax elements that are supported by some of the procedures in this book. In some cases, individual procedures implement these common elements in slightly different ways. When this occurs, the differences are described in the respective procedure chapters.

The section “[Details for SAS Econometrics Procedures](#)” on page 89 provides details that are common to some of the procedures in this book.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;  
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS statement and the LIBNAME statement, see *SAS Cloud Analytic Services: User's Guide*. For general information about CAS and CAS sessions, see *SAS Cloud Analytic Services: Fundamentals*.

Loading a SAS Data Set onto a CAS Server

Procedures in this book require the input data to reside on a CAS server. To work with a SAS data set, you must first load the data set onto the CAS server. Data loaded on the CAS server are called *data tables*. This section lists three methods of loading a SAS data set onto a CAS server. In this section, `mylib` is the name of the caslib that is connected to the `mysess` CAS session.

- You can use a single DATA step to create a data table on the CAS server as follows:

```
data mylib.Sample;
  input y x @@;
  datalines;
.46 1 .47 2 .57 3 .61 4 .62 5 .68 6 .69 7
;
```

Note that DATA step operations might not work as intended when you perform them on the CAS server instead of the SAS client.

- You can create a SAS data set first, and when it contains exactly what you want, you can use another DATA step to load it onto the CAS server as follows:

```
data Sample;
  input y x @@;
  datalines;
.46 1 .47 2 .57 3 .61 4 .62 5 .68 6 .69 7 .78 8
;
data mylib.Sample;
  set Sample;
run;
```

- You can use the CASUTIL procedure as follows:

```
proc casutil sessref=mysess;
  load data=Sample casout="Sample";
quit;
```

The CASUTIL procedure can load data onto a CAS server more efficiently than the DATA step. For more information about the CASUTIL procedure, see *SAS Cloud Analytic Services: User's Guide*.

The `mylib` caslib stores the `Sample` data table, which can be distributed across many machine nodes. You must use a caslib reference in procedures in this book to enable the SAS client machine to communicate with the CAS session. For example, the following SEVSELECT procedure statements use a data table that resides in the `mylib` caslib:

```
proc sevselect data = mylib.Sample;
  ...statements...;
run;
```

You can delete your data table by using the DELETE procedure as follows:

```
proc delete data = mylib.Sample;
run;
```

The Sample data table is accessible only in the mysess session. When you terminate the mysess session, the Sample data table is no longer accessible from the CAS server. If you want your Sample data table to be available to other CAS sessions, then you must *promote* your data table. For more information about data tables, see *SAS Cloud Analytic Services: User's Guide*.

Syntax Common to SAS Econometrics Procedures

CLASS Statement

```
CLASS variable <(options)> . . . <variable <(options)> > > </ global-options> ;
```

This section applies to the following procedures: CNTSELECT, CPANEL, CQLIM, CSPATIALREG, and SEVSELECT.

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. These variables enter the analysis not through their values, but through levels to which the unique values are mapped. For more information about these mappings, see the section “[Levelization of Classification Variables](#)” on page 89.

If the procedure permits a classification variable as a response (dependent variable or target), the response does not need to be specified in the CLASS statement.

You can specify options either as individual variable *options*, by enclosing the options in parentheses after the variable name, or as *global-options*, by placing them after a slash (/). *Global-options* are applied to all variables that are specified in the CLASS statement. If you specify more than one CLASS statement, the *global-options* that are specified in any one CLASS statement apply to all CLASS statements. However, individual CLASS variable *options* override the *global-options*.

Table 4.1 summarizes the values you can use for either an *option* or a *global-option*. The options are described in detail in the list that follows Table 4.1.

Table 4.1 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable
SPLIT	Splits levels of CLASS variables into independent effects

DESCENDING**DESC**

reverses the sort order of the classification variable. If both the DESCENDING and **ORDER=** options are specified, the procedure orders the categories according to the **ORDER=** option and then reverse that order.

MISSING

treats missing values (“.”, “.A”, . . . , “.Z” for numeric variables and blanks for character variables) as valid values for the CLASS variable.

If you do not specify the MISSING option, observations that have missing values for CLASS variables are removed from the analysis.

ORDER=FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of classification variables. This order determines which parameters in the model correspond to each level in the data. The following table shows how to interpret values of the **ORDER=** keywords:

Value of ORDER=	Levels Sorted By
FORMATTED	External formatted values, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) values. The sort order is machine-dependent. For numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values.
FREQ	Descending frequency count (levels that have more observations come earlier in the order)
INTERNAL	Unformatted value. The sort order is machine-dependent.

The **ORDER=** option does not apply to missing values, which are always ordered first.

For more information about sort order, see the chapter about the SORT procedure in *Base SAS Procedures Guide* and the discussion of BY-group processing in the “Grouping Data” section of *SAS Programmers Guide: Essentials*. By default, **ORDER=FORMATTED**.

PARAM=keyword

specifies the parameterization method for the classification variable or variables. You can specify any of the *keywords* shown in the following table; design matrix columns are created from CLASS variables according to the corresponding coding schemes.

Table 4.2 Value of **PARAM=**

Value of PARAM=	Coding
EFFECT	Effect coding. The REF= option in the CLASS statement determines the reference level.
GLM	Less-than-full-rank reference cell coding. This <i>keyword</i> can be used only as a <i>global-option</i> and is applied to all CLASS variables; all other individual variable parameterization specifications are ignored. The REF= option in the CLASS statement indirectly determines the reference level through the order of levels.

Table 4.2 *continued*

Value of PARAM=	Coding
ORDINAL THERMOMETER	Cumulative parameterization for an ordinal CLASS variable
POLYNOMIAL POLY	Polynomial coding. If the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used.
REFERENCE REF	Reference cell coding. The REF= option in the CLASS statement determines the reference level.
ORTHEFFECT	Orthogonalizes PARAM=EFFECT coding. The REF= option in the CLASS statement determines the reference level.
ORTHORDINAL ORTHOTHERM	Orthogonalizes PARAM=ORDINAL coding
ORTHPOLY	Orthogonalizes PARAM=POLYNOMIAL coding. If the classification variable is numeric, then the ORDER= option in the CLASS statement is ignored, and the internal unformatted values are used.
ORTHREF	Orthogonalizes PARAM=REFERENCE coding. The REF= option in the CLASS statement determines the reference level.

All parameterizations are full rank, except for the GLM parameterization. If you specify a full rank parameterization for any CLASS variable, then every CLASS variable without a specified coding is given the EFFECT coding.

By default, PARAM=GLM. For more information about how parameterization of classification variables affects the construction and interpretation of model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91.

REF='level' | *keyword*

REFERENCE='level' | *keyword*

specifies the reference level that is used when you specify a nonsingular parameterization. You can specify the following values:

'level' specifies the *level* of the variable to use as the reference level. Specify the formatted value of the variable if a format is assigned. You can specify this value only for an individual variable *option*.

FIRST designates the first ordered level as reference. You can specify this value either for an individual variable *option* or for a *global-option*.

LAST designates the last ordered level as reference. You can specify this value either for an individual variable *option* or for a *global-option*.

By default, REF=LAST.

SPLIT

specifies that design matrix columns that correspond to any effect that contains a split classification variable can be selected to enter or leave a model independently of the other design columns of that effect. This option applies to procedures that perform model selection.

Suppose that the variable `temp` has three levels ('hot', 'warm', and 'cold'), that the variable `gender` has two levels ('M' and 'F'), and that the variables are used in a PROC SEVSELECT run as follows:

```
proc sevselect data=mylib.data;
  loss y;
  class temp gender / split;
  scalemodel gender gender*temp;
run;
```

The two effects in the SCALEMODEL statement are split into eight independent effects. The effect “gender” is split into two effects that are labeled “gender_M” and “gender_F”. The effect “gender*temp” is split into six effects that are labeled “gender_M*temp_hot”, “gender_F*temp_hot”, “gender_M*temp_warm”, “gender_F*temp_warm”, “gender_M*temp_cold”, and “gender_F*temp_cold”. The previous PROC SEVSELECT step is equivalent to the following:

```
proc sevselect data=mylib.data;
  loss y;
  scalemodel gender_M gender_F
             gender_M*temp_hot gender_F*temp_hot
             gender_M*temp_warm gender_F*temp_warm
             gender_M*temp_cold gender_F*temp_cold;
run;
```

The SPLIT option can be used on individual classification variables. For example, consider the following PROC SEVSELECT step:

```
proc sevselect data=mylib.data;
  loss y;
  class temp(split) gender;
  scalemodel gender gender*temp;
run;
```

In this case, the effect “gender” is not split and the effect “gender*temp” is split into three effects, which are labeled “gender*temp_hot”, “gender*temp_warm”, and “gender*temp_cold”. Furthermore, each of these three split effects now has two parameters that correspond to the two levels of “gender.” The PROC SEVSELECT step is equivalent to the following:

```
proc sevselect data=mylib.data;
  loss y;
  class gender;
  scalemodel gender gender*temp_hot gender*temp_warm gender*temp_cold;
run;
```

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

This section applies to the following procedures: CCDM, CCOPULA, CNTSELECT, CPANEL, CQLIM, CSPATIALREG, ECM, HMM, and SEVSELECT.

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the specific procedure chapters. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

This section applies to the following procedures: CCDM, CCOPULA, CNTSELECT, CPANEL, CQLIM, CSPATIALREG, ECM, HMM, and SEVSELECT.

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The table names that you can specify are listed in the specific procedure chapters.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

EFFECT Statement

EFFECT *effect-name* = *effect-type* (*var-list* < / *effect-options* >) ;

This section applies to the following procedures: CNTSELECT and SEVSELECT.

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are called *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section “GLM Parameterization of Classification Variables and Effects” on page 94. For example, the terms A, B, x, A*x, and A*B in the following statements define fixed effects of the usual type in a generalized linear model:

```
proc sevselect;
  loss y;
  class A B;
  scalemodel A B x A*x;
run;
```

A constructed effect, on the other hand, is assigned through the EFFECT statement. For example, in the following program, the EFFECT statement defines a constructed effect named spl:

```
proc sevselect;
  loss y;
  class A B;
  effect spl = spline(x);
  scalemodel A B A*spl;
run;
```

The columns of spl are formed from the data set variable x as a cubic B-spline basis with three equally spaced interior knots.

Each constructed effect corresponds to a collection of columns that are referred to by the name you supply. You can specify multiple EFFECT statements, and all EFFECT statements must precede the SCALEMODEL statement in the SEVSELECT procedure or the MODEL statement in other procedures.

You must specify the following arguments:

effect-name

names the effect. This name can appear in only one EFFECT statement and cannot be the name of a variable in the input data set.

effect-type

specifies the type of effect. You can specify the following *effect-types*:

COLLECTION

specifies a collection effect that defines one or more variables as a single effect that has multiple degrees of freedom. The variables in a collection are considered as a unit for purposes of estimation and inference. For more information, see the section “Collection Effects” on page 64.

MULTIMEMBER MM	specifies a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement. For more information, see the section “ Multimember Effects ” on page 64.
POLYNOMIAL POLY	specifies a multivariate polynomial effect in the specified numeric variables. For more information, see the section “ Polynomial Effects ” on page 66.
SPLINE	specifies a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables. For more information, see the section “ Spline Effects ” on page 69.

var-list

specifies a list of variables that are used in constructing the effect. You can also specify any of the *effect-options* that are shown in [Table 4.3](#) after a slash following the *var-list*.

Table 4.3 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Multimember Effects Options	
DETAILS	Displays the levels of the multimember effect
NOEFFECT	Specifies that observations whose levels are all missing for the multimember variables should have 0 values in the corresponding design matrix columns
STDIZE	Standardizes the design matrix entries so that each observation has a sum of 1
WEIGHT=	Specifies the weight variable for the contributions of each classification effect
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
DETAILS	Displays details of the specified polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
NOSEPARATE	Treats the polynomial as a single effect with multiple degrees of freedom
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial

Table 4.3 *continued*

Option	Description
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline effect
DATABOUNDARY	Uses the extremes of the data as boundary knots for a B-spline basis
DEGREE=	Specifies the degree of the spline effect
DETAILS	Displays the knots and locations for each spline basis function
KNOTMAX=	Requests equally spaced right-side boundary knots starting at the variables' maximum and ending at the KNOTMAX= value
KNOTMETHOD=	Specifies how to construct the knots for the spline effect
KNOTMIN=	Requests equally spaced left-side boundary knots starting at the KNOTMIN= value and ending at the variables' minimum value
NATURALCUBIC	Specifies a natural cubic spline basis for the spline effect
SEPARATE	Treats the spline basis for each variable as a separate effect when multiple variables are specified
SPLIT	Treats each design matrix column as a separate effect for selection methods

Collection Effects

EFFECT *effect-name*=**COLLECTION** (*var-list* < / **DETAILS** >) ;

You use a collection effect to define a set of variables that are treated as a single effect that has multiple degrees of freedom. The variables in *var-list* can be continuous or classification variables. Columns in the design matrix that are contributed by a collection effect are the design columns of its constituent variables in the order in which they appear in the definition of the collection effect. If you specify the **DETAILS** option, then a table that shows the constituents of the collection effect is displayed.

Multimember Effects

EFFECT *effect-name*=**MULTIMEMBER** (*var-list* < / *mm-options* >) ;

EFFECT *effect-name*=**MM** (*var-list* < / *mm-options* >) ;

A multimember effect is formed from one or more classification variables in such a way that each observation can be associated with one or more levels of the union of the levels of the classification variables. In other words, a multimember effect is a classification-type effect with possibly more than one nonzero column entry for each observation. Multimember effects are useful, for example, in modeling the following:

- nurses' effects on patient recovery in hospitals
- teachers' effects on student scores
- lineage effects in genetic studies

The levels of a multimember effect consist of the union of formatted values of the variables that define this effect. Each such level contributes one column to the design matrix. For each observation, the value that

corresponds to each level of the multimember effect in the design matrix is the number of times that this level occurs for the observation.

For example, the following data provide teacher information and end-of-year test scores for students after two semesters:

Student	Score	Teacher1	Teacher2
Mary	87	Tobias	Cohen
Tom	89	Rodriguez	Tobias
Fred	82	Cohen	Cohen
Jane	88	Tobias	.
Jack	99	.	.

For example, Mary had different teachers in the two semesters, Fred had the same teacher in both semesters, and Jane received instruction only in the first semester.

You can model the effect of the teachers on student performance by specifying a multimember effect as follows:

```
CLASS teacher1 teacher2;
EFFECT teacher = MM(teacher1 teacher2);
```

The levels of the teacher effect are Cohen, Rodriguez, and Tobias, and the associated design matrix columns are as follows:

Student	Cohen	Rodriguez	Tobias
Mary	1	0	1
Tom	0	1	1
Fred	2	0	0
Jane	0	0	1
Jack	.	.	.

You can specify the following *mm-options* after a slash (/):

DETAILS

displays a table that shows the levels of the multimember effect.

NOEFFECT

specifies that, for observations of the multimember variables whose levels are all missing, the values in the corresponding design matrix columns be set to 0. If, in the preceding example, the teacher effect is defined by the following statement, then the associated design matrix columns' values for Jack are all 0:

```
EFFECT teacher = MM(teacher1 teacher2 / noeffect);
```

This statement enables you to include Jack in the analysis even though there is no effect of teachers on his performance.

A situation where it is important to designate observations as having no effect that can be attributed to a classification variable is the analysis of crossover designs, where lagged treatment levels are used to model the carryover effects of treatments between periods. Because there is no carryover effect for the first period, the treatment lag effect in a crossover design can be modeled by using a multimember effect that consists of a single classification variable and the NOEFFECT option, as in the following statements:

```
CLASS Treatment lagTreatment;
EFFECT Carryover = MM(lagTreatment / noeffect);
```

The lagTreatment variable contains a missing value for the first period. Otherwise, it contains the value of the treatment variable for the preceding period.

STDIZE

specifies that for each observation, the entries in the design matrix that corresponds to the multimember effect be scaled to have a sum of 1.

WEIGHT=*weight-list*

specifies numeric variables used to weigh the contributions of each of the classification effects that define the constructed multimember effect. The number of variables in *weight-list* must match the number of classification variables that define the effect.

Polynomial Effects

```
EFFECT effect-name=POLYNOMIAL (var-list </ polynomial-options>);
```

```
EFFECT effect-name=POLY (var-list </ polynomial-options>);
```

The variables in *var-list* must be numeric. A design matrix column is generated for each term of the specified polynomial. By default, each of these terms is treated as a separate effect for the purpose of model building. For example, the following two PROC sevselect,upper() steps yield the identical analysis:

```
proc sevselect;
  loss y;
  effect MyPoly = polynomial(x1-x3/degree=2);
  scalemodel MyPoly;
run;

proc sevselect;
  loss y;
  scalemodel x1 x2 x3 x1*x1 x1*x2 x1*x3 x2*x2 x2*x3 x3*x3;
run;
```

You can specify the following *polynomial-options* after a slash (/):

DEGREE=*n*

specifies the degree of the polynomial, where *n* must be a positive integer and is typically a small integer, such as 1, 2, or 3. By default, DEGREE=1.

DETAILS

displays a table that shows the details of the specified polynomial, including the number of terms generated. If you also specify the [STANDARDIZE](#) option, then a table that shows the standardization details is also produced.

MDEGREE=*n*

specifies the maximum degree of any variable in a term of the polynomial, where *n* must be a positive integer. The default is the degree of the specified polynomial. For example, the following statement generates the terms x_1 , x_2 , x_1^2 , x_1x_2 , x_2^2 , $x_1^2x_2$, $x_1x_2^2$ and $x_1^2x_2^2$:

```
EFFECT MyPoly=POLYNOMIAL(x1 x2/degree=4 MDEGREE=2);
```

NOSEPARATE

treats the polynomial as a single effect that has multiple degrees of freedom. The *effect-name* that you specify is used as the constructed effect name, and the labels of the terms are used as labels of the corresponding parameters.

STANDARDIZE <(*centerscale-opts*)> <= *standardize-opt*>

standardizes the variables that define the polynomial. By default, the standardized variables receive prefix “s_” in the variable names.

You can use the following *centerscale-opts* to specify how the center and scale are estimated:

METHOD=MOMENTS

estimates the center by the variable mean and the scale by the standard deviation. If a weight variable is specified using a WEIGHT statement, the weights are not used in the computation of the mean and standard deviation, and observations that have invalid weights are ignored. Only observations that are used in performing the analysis are used for the standardization.

METHOD=RANGE

estimates the center by the midpoint of the variable range and the scale as half the variable range. Any observation that has a missing value for any regressor used in the model is ignored when the range of variables in a polynomial effect is computed. Observations that have valid regressor values but missing or invalid values of frequency variables, weight variables, or dependent variables are used in computing variable ranges. By default, METHOD=RANGE.

METHOD=WMOMENTS

is the same as METHOD=MOMENTS except that weighted means and weighted standard deviations are used.

PREFIX=NONE | *quoted-string*

specifies the prefix that is appended to standardized variables when forming the term labels. You can specify the following values:

quoted-string specifies the prefix
NONE does not apply a prefix

By default, PREFIX="s_".

Let

n = number of observations used in the analysis
 w = weight variable
 f = frequency variable
 x = variable to be standardized
 $x_{(n)}$ = $\text{Max}_{i=1}^n(x_i)$
 $x_{(1)}$ = $\text{Min}_{i=1}^n(x_i)$
 F = sum of frequencies
 $= \sum_{i=1}^n f_i$
WF = sum of weighted frequencies
 $= \sum_{i=1}^n w_i f_i$

Table 4.4 shows how the center and scale are computed for each of the supported methods.

Table 4.4 Center and Scale Estimates by Method

Method	Center	Scale
RANGE	$(x_{(n)} + x_{(1)})/2$	$(x_{(n)} - x_{(1)})/2$
MOMENTS	$\bar{x} = \sum_{i=1}^n f_i x_i / F$	$\sqrt{\sum_{i=1}^n f_i (x_i - \bar{x})^2 / (F - 1)}$
WMOMENTS	$\bar{x}_w = \sum_{i=1}^n w_i f_i x_i / \text{WF}$	$\sqrt{\sum_{i=1}^n w_i f_i (x_i - \bar{x}_w)^2 / (F - 1)}$

You can control whether the standardization is to center, scale, or both center and scale by specifying one of the following *standardize-opts*:

CENTER

centers but does not scale the variables. For a variable x ,

$$s_x = x - \text{center}$$

CENTERSCALE

centers and scales the variables. This is the default if you do not specify a *standardization-opt*.

For a variable x ,

$$s_x = \frac{x - \text{center}}{\text{scale}}$$

NONE

performs no standardization.

SCALE

scales but does not center the variables. For a variable x ,

$$s_x = \frac{x}{\text{scale}}$$

Spline Effects

This section discusses the construction of spline effects through the EFFECT statement. A spline effect expands variables into spline bases whose form depends on the options that you specify. For more information about regression splines and spline bases, see the section “[Splines and Spline Bases](#)” on page 72. You request a spline effect with the syntax

EFFECT *name*=**SPLINE** (*var-list* < / *spline-options* >) ;

The variables in *var-list* must be numeric. Design matrix columns are generated separately for each of these variables, and the set of columns is collectively referred to with the specified name. By default, the spline basis that is generated for each variable is a cubic B-spline basis that has three equally spaced knots positioned between the minimum and maximum values of that variable. This yields by default seven design matrix columns for each of the variables in the SPLINE effect.

You can specify the following *spline-options* after a slash (/):

BASIS=BSPLINE

uses a B-spline basis for the spline expansion. For splines of degree d that are defined with n knots, this basis consists of $n + d + 1$ columns. In order to completely specify the B-spline basis, d left-side boundary knots and $\max\{d, 1\}$ right-side boundary knots are also required. For information about how to specify the positions of both the internal and boundary knots, see the [KNOTMETHOD=](#), [DATABOUNDARY](#), [KNOTMIN=](#), and [KNOTMAX=](#) suboptions.

BASIS=TPF(*options*)

specifies a truncated power function basis for the spline expansion. For splines of degree d that are defined with n knots for a variable x , this basis consists of an intercept, polynomials $x, x^2, \dots, x^d$, and one truncated power function for each of the n knots. Unlike the B-spline basis, no boundary knots are required. For information about how you can specify the position of the internal knots, see the [KNOTMETHOD=](#) suboption.

You can modify the number of columns when you request BASIS=TPF by specifying the following *options*:

NOINT excludes the intercept column.

NOPOWERS excludes the intercept and polynomial columns.

By default, BASIS=BSPLINE.

DATABOUNDARY

uses the extremes of the data as boundary knots when building a B-spline basis.

DEGREE=*n*

specifies the degree of the spline transformation, where *n* must be a nonnegative integer and is typically a small integer, such as 0, 1, 2, or 3. By default, DEGREE=3.

DETAILS

displays tables that show the knot locations and the knots associated with each spline basis function.

KNOTMAX=*value*

requests that, for each variable in the EFFECT statement, the right-side boundary knots be equally spaced starting at the maximum of the variable and ending at the specified value. This option is ignored for variables whose maximum value is greater than the specified value or if the **DATABOUNDARY** option is also specified.

KNOTMETHOD=*knot-method* < (*knot-options*) >

specifies how to construct the knots for spline effects. You can choose from the following *knot-methods* and affect the knot construction further with the method-specific *knot-options*:

EQUAL < (*n*) >

specifies that *n* equally spaced knots be positioned between the extremes of the data. By default, *n* = 3. For a B-spline basis, any needed boundary knots continue to be equally spaced unless the **DATABOUNDARY** option has also been specified. By default, KNOTMETHOD=EQUAL(3).

LIST(*number-list*)

specifies the list of internal knots to be used in forming the spline basis columns. For a B-spline basis, the data extremes are used as boundary knots.

LISTWITHBOUNDARY(*number-list*)

specifies the list of all knots that are used in forming the spline basis columns. When you use a truncated power function basis, this list is interpreted as the list of internal knots. When you use a B-spline basis of degree *d*, then the first *d* entries are used as left-side boundary knots and the last max(*d*, 1) entries in the list are used as right-side boundary knots.

MULTISCALE < (*multiscale-options*) >

generates multiple B-spline bases, which correspond to sets that have an increasing number of internal knots. As the number of internal knots increases, the spline basis that is generated can approximate features of the data at finer scales. So generating bases at multiple scales facilitates the modeling of both coarse- and fine-grained features of the data. For scale *i*, the spline basis corresponds to 2^i equally spaced internal knots. By default, the bases for scales 0–7 are generated. For each scale, a separate spline effect is generated. The name of the constructed spline effect at scale *i* is formed by appending *_Si* to the effect name that you specify in the EFFECT statement. If you specify multiple variables in the EFFECT statement, then spline bases are generated separately for each variable at each scale and the name of the corresponding effect is obtained by appending the variable name followed by *_Si* to the name in the EFFECT statement. For example, the following statement generates effects named spl_x1_S0, spl_x1_S1, spl_x1_S2, . . . , spl_x1_S7 and spl_x2_S1, spl_x2_S2, . . . , spl_x2_S7:

```
EFFECT spl = spline(x1 x2 / knotmethod=multiscale);
```

The MULTISCALE option is ignored if you specify the BASIS=TPF *spline-option*.

The following *multiscale-options* control which scales are included:

STARTSCALE=*n* specifies the start scale, where *n* is a positive integer. By default, STARTSCALE=0.

ENDSCALE=*n* specifies the end scale, where *n* is a positive integer. By default, ENDSCALE=7.

PERCENTILES(*n*)

requests that internal knots be placed at *n* equally spaced percentiles of the variable or variables named in the EFFECT statement. For example, the following statement positions internal knots at the deciles of the variable x. For a B-spline basis, the extremes of the data are used as boundary knots:

```
EFFECT spl = spline(x / knotmethod=percentiles(9));
```

RANGEFRACTIONS(*fraction-list*)

places internal knots at each fraction of the ranges of the variables in the EFFECT statement. For example, if variable x1 ranges between 1 and 3 and variable x2 ranges between 0 and 20, then the following EFFECT statement uses internal knots 1.2, 2, and 2.5 for variable x1 and internal knots 2, 10, and 15 for variable x2:

```
EFFECT spl = spline(x1 x2 / knotmethod=rangefractions(.1 .5 .75));
```

For a B-spline basis, the data extremes are used as boundary knots.

KNOTMIN=*value*

requests that, for each variable in the EFFECT statement, the left-side boundary knots be equally spaced starting at the specified value and ending at the minimum of the variable. This option is ignored for variables whose minimum value is less than the specified value or if the DATABOUNDARY option is also specified.

NATURALCUBIC

uses a natural cubic spline basis for the spline expansion. Natural cubic splines, also known as restricted cubic splines, are cubic splines that are constrained to be linear beyond the extreme knots. The natural cubic spline basis that is produced by the EFFECT statement is obtained by starting from the unrestricted truncated power function cubic spline basis that is defined with *n* distinct knots and imposes the linearity constraints beyond the extreme knots. This basis consists of an intercept, the polynomial *x*, and *n* – 2 functions that are all linear beyond the largest knot. The *i*th function, *i* = 1, 2, ..., *n* – 2, is 0 to the left of the *i*th knot, which is called the “break knot.” For more information about this basis, see the section “[Splines and Spline Bases](#)” on page 72. You can use the NOINT and NOPOWERS suboptions of the BASIS=TPF option to suppress the intercept and polynomial *x* when the columns of the natural cubic spline basis are formed. When you specify the NATURALCUBIC option, the options BASIS=BSPLINE, DATABOUNDARY, DEGREE=, and KNOTMETHOD=MULTISCALE are not applicable.

SEPARATE

requests that, when multiple variables are specified in the EFFECT statement, the spline basis for each variable be treated as a separate effect. The names of these separated effects are formed by appending an underscore followed by the name of the variable to the name that you specify in the EFFECT statement. For example, the following statement generates the effect names spl_x1 and spl_x2:

```
EFFECT spl = spline(x1 x2 / separate);
```

In procedures that support variable selection, such as the SEVSELECT procedure, these two effects can enter or leave the model independently during the selection process.

SPLIT

treats each individual column in the design matrix that corresponds to the spline effect as a separate effect that can enter or leave the model independently. Names for these split effects are generated by appending the variable name and an index for each column to the name that you specify in the EFFECT statement. For example, the effects generated for the spline effect in the following statement are spl_x1:1, spl_x1:2, ..., spl_x1:7 and spl_x2:1, spl_x2:2, ..., spl_x2:7:

```
EFFECT spl = spline(x1 x2 / split);
```

Splines and Spline Bases

This section provides details about how the EFFECT statement constructs spline bases. A spline function is a piecewise polynomial function in which the individual polynomials have the same degree and connect smoothly at join points whose abscissa values, called knots, are prespecified. You can use spline functions to fit curves to a wide variety of data.

A spline of degree 0 is a step function with steps located at the knots. A spline of degree 1 is a piecewise linear function where the lines connect at the knots. A spline of degree 2 is a piecewise quadratic curve whose values and slopes coincide at the knots. A spline of degree 3 is a piecewise cubic curve whose values, slopes, and curvature coincide at the knots. Visually, a cubic spline is a smooth curve, and it is the most commonly used spline when a smooth fit is desired. Note that when no knots are used, splines of degree d are simply polynomials of degree d .

More formally, suppose you specify knots $k_1 < k_2 < k_3 < \dots < k_n$. Then a spline of degree $d \geq 0$ is a function $S(x)$ with $d-1$ continuous derivatives such that

$$S(x) = \begin{cases} P_0(x) & x < k_1 \\ P_i(x) & k_i \leq x < k_{i+1}; i = 1, 2, \dots, n-1 \\ P_n(x) & x \geq k_n \end{cases}$$

where each $P_i(x)$ is a polynomial of degree d . The requirement that $S(x)$ has $d-1$ continuous derivatives is satisfied by requiring that the function values and all derivatives up to order $d-1$ of the adjacent polynomials at each knot match.

A counting argument yields the number of parameters that define a spline with n knots. There are $n+1$ polynomials of degree d , producing $(n+1)(d+1)$ coefficients. However, there are d restrictions at each of the n knots, so the number of free parameters is $(n+1)(d+1) - nd = n + d + 1$. In mathematical terminology this says that the dimension of the vector space of splines of degree d on n distinct knots is $n + d + 1$.

+ 1. If you have $n + d + 1$ basis vectors, then you can fit a curve to your data by regressing your dependent variable by using this basis for the corresponding design matrix columns. In this context, such a spline is known as a regression spline. The EFFECT statement provides a simple mechanism for obtaining such a basis.

If you remove the restriction that the knots of a spline must be distinct and allow repeated knots, then you can obtain functions that have less smoothness and even discontinuities at the repeated knot location. For a spline of degree d and a repeated knot that has multiplicity $m \leq d$, the piecewise polynomials that join such a knot are required to have only $d - m$ matching derivatives. Note that this increases the number of free parameters by $m - 1$ but also decreases the number of distinct knots by $m - 1$. Hence the dimension of the vector space of splines of degree d with n knots is still $n + d + 1$, provided that any repeated knot has a multiplicity less than or equal to d .

The EFFECT statement supports the commonly used *truncated power function* basis and *B-spline* basis. With exact arithmetic and by using the complete basis, you obtain the same fit with either of these bases. The following subsections provide details about constructing spline bases for the space of splines of degree d with n knots that satisfies $k_1 \leq k_2 \leq k_3 < \dots \leq k_n$.

Truncated Power Function Basis

A truncated power function for a knot k_i is a function defined by

$$t_i(x) = \begin{cases} 0 & x < k_i \\ (x - k_i)^d & x \geq k_i \end{cases}$$

Figure 4.1 shows such functions for $d = 1$ and $d = 3$ with a knot at $x = 1$.

Figure 4.1 Truncated Power Functions with Knot at $x = 1$

The name is derived from the fact that these functions are shifted power functions that are truncated to 0 to the left of the knot. These functions are piecewise polynomial functions that have two pieces whose function values and derivatives of all orders up to $d-1$ are 0 at the defining knot. Hence these functions are splines of degree d . It is easy to see that these n functions are linearly independent. However, they do not form a basis, because such a basis requires $n+d-1$ functions. The usual way to add $d+1$ additional basis functions is to use the polynomials $1, x, x^2, \dots, x^d$. These $d+1$ functions together with the n truncated power functions $t_i(x), i = 1, 2, \dots, n$ form the truncated power basis.

Note that each time a knot is repeated, the associated exponent used in the corresponding basis function is reduced by 1. For example, for splines of degree d with three repeated knots $k_i = k_{i+1} = k_{i+2}$, the corresponding basis functions are $t_i(x) = (x - k_i)_+^d$, $t_{i+1}(x) = (x - k_i)_+^{d-1}$, and $t_{i+2}(x) = (x - k_i)_+^{d-2}$. Provided that the multiplicity of each repeated knot is less than or equal to the degree, this construction continues to yield a basis for the associated space of splines.

The main advantage of the truncated power function basis is the simplicity of its construction and the ease of interpreting the parameters in a model that corresponds to these basis functions. However, there are two weaknesses when you use this basis for regression. These functions grow rapidly without bound as x increases, resulting in numerical precision problems when the x data span a wide range. Furthermore, many or even all of these basis functions can be nonzero when evaluated at some x value, resulting in a design matrix that has few zeros and precludes the use of sparse matrix technology to speed up computation. This weakness can be addressed by using a B-spline basis.

B-Spline Basis

A B-spline basis can be built by starting with a set of Haar basis functions, which are functions that are 1 between adjacent knots and 0 elsewhere, and then applying a simple linear recursion relationship d times, yielding the $n + d + 1$ needed basis functions. For the purpose of building the B-spline basis, the n prespecified knots are called internal knots. This construction requires d additional knots, known as boundary knots, to be positioned to the left of the internal knots, and $\max(d, 1)$ boundary knots to be positioned to the right of the internal knots. The actual values of these boundary knots can be arbitrary. The EFFECT statement provides several methods for placing the necessary boundary knots, including the common method of using repeated values of the data extremes as the boundary knots. The boundary knot placement affects the precise form of the basis functions that are generated, but it does not affect the following two desirable properties:

- The B-spline basis functions are nonzero over an interval that spans at most $d + 2$ knots. This yields design matrix columns each of whose rows contain at most $d + 2$ adjacent nonzero entries.
- The computation of the basis functions at any x value is numerically stable and does not require evaluating powers of this value.

The following figures show the B-spline bases that are defined on $[0, 1]$ with four equally spaced internal knots at 0.2, 0.4, 0.6, and 0.8.

Figure 4.2 shows a linear B-spline basis. This basis consists of six functions, each of which is nonzero over an interval that spans at most three knots.

Figure 4.2 Linear B-Spline Basis with Four Equally Spaced Interior Knots

Figure 4.3 shows a cubic B-spline basis where the necessary boundary knots are positioned at $x = 0$ and $x = 1$. This basis consists of eight functions, each of which is nonzero over an interval that spans at most five knots.

Figure 4.3 Cubic B-Spline Basis with Four Equally Spaced Interior Knots

Figure 4.4 shows a different cubic B-spline basis where the necessary left-side boundary knots are positioned at -0.6 , -0.4 , -0.2 , and 0 . The right-side boundary knots are positioned at 1 , 1.2 , 1.4 , and 1.6 . As in the basis shown in Figure 4.3, this basis consists of eight functions, each of which is nonzero over an interval that spans at most five knots. The different positioning of the boundary knots has merely changed the shape of the individual basis functions.

Figure 4.4 Cubic B-Spline Basis with Equally Spaced Boundary and Interior Knots

For more information about this construction, see Hastie, Tibshirani, and Friedman (2001).

Natural Cubic Spline Basis

Natural cubic splines are cubic splines with the additional restriction that the splines are required to be linear beyond the extreme knots. Some authors prefer the terminology “restricted cubic splines” to “natural cubic splines.” The space of unrestricted cubic splines on n knots has the dimension $n + 4$. Imposing the restrictions that the cubic polynomials beyond the first and last knot reduce to linear polynomials reduces the number of degrees of freedom by 4, so a basis for the natural cubic splines consists of n functions. Starting from the truncated power function basis for the unrestricted cubic splines, you can obtain a reduced basis by imposing linearity constraints. For more information about this construction, see Hastie, Tibshirani, and Friedman (2001). [Figure 4.5](#) shows this natural cubic spline basis defined on $[0, 1]$ with four equally spaced internal knots at 0.2, 0.4, 0.6, and 0.8. This basis consists of four basis functions that are all linear beyond the extreme knots at 0.2 and 0.8.

Figure 4.5 Natural Cubic Spline Basis with Four Equally Spaced Knots

ODS Table Names

Each constructed effect produces one or more informative tables when the DETAILS option is also specified. Each table has a name associated with it. This name is used to refer to the table by procedures that support a DISPLAY or DISPLAYOUT statement. You also use this name to refer to the table in ODS statements. These names are listed in [Table 4.5](#).

Table 4.5 ODS Tables Produced by the EFFECT Statement

Table Name	Description	Option
BSplineDetails	B-spline basis details	BASIS=BSPLINE
CollectionLevelInfo	Levels of collection effects	
MMLevelInfo	Levels of multimember effects	
PolyDetails	Number of variables and columns, polynomial degree, and standardization method	
PolyScaling	Centering and scaling details	STANDARDIZE
SplineKnots	knot and boundary knot values	
TPFSplineDetails	Truncated power function spline basis details	BASIS=TPF or NATURALCUBIC

SELECTION Statement

SELECTION < **METHOD**=*method*< (*method-options*)> >> *options*> ;

This section applies to the following procedures: CNTSELECT and SEVSELECT.

Procedures in this book that support model selection use the SELECTION statement to control details about the model selection process.

You can specify the following methods in the SELECTION statement:

METHOD=*method* < (*method-options*)>

specifies the method to be used to select the model. You can also specify *method-options* to apply to the specified method by enclosing them in parentheses after the *method*.

The following *methods* are available and are explained in detail in the section “[Model Selection Methods](#)” on page 102. By default, METHOD=STEPWISE.

BACKWARD	specifies backward elimination. This method starts with all effects in the model and deletes effects.
FORWARD	specifies forward selection. This method starts with no effects in the model and adds effects.
FORWARDSSWAP	specifies forward-swap selection, which is an extension of the forward selection method. Before any addition step, the procedure makes all pairwise swaps of one effect in the model and one effect out of the current model that improve the selection criterion.
MCP	specifies the MCP method, which minimizes ordinary least squares plus the mini-max concave penalty (MCP) function. As an alternative to the convex penalized methods such as LASSO and ELASTICNET, MCP is one of the nonconvex penalized methods.
NONE	specifies no model selection.
SCAD	specifies the SCAD method, which minimizes ordinary least squares plus the smoothly clipped absolute deviation (SCAD) function. As an alternative to the convex penalized methods such as LASSO and ELASTICNET, SCAD is one of the nonconvex penalized methods.
STEPWISE	specifies stepwise regression. This method is similar to the FORWARD method except that effects already in the model do not necessarily stay there.

[Table 4.6](#) lists the applicable *method-options* for each of these methods.

Table 4.6 Applicable *method-options* by *method*

<i>method-option</i>	FORWARD	BACKWARD	STEPWISE
CHOOSE =	x	x	x
COMPETITIVE			x
CRITERION =	x	x	x
MAXEFFECTS =	x		x
MAXSTEPS =	x	x	x
MINEFFECTS =		x	
SELECT =	x	x	x
STOP =	x	x	x

The syntax of the *method-options* that you can specify in parentheses after the **SELECTION=** option *method* follows. As described in Table 4.6, not all selection *method-options* are applicable to every *method*.

CHOOSE=criterion

chooses from the list of models (at each step of the selection process) the model that yields the best value of the specified criterion. If the optimal value of the specified criterion occurs for models at more than one step, then the model that has the smallest number of parameters is chosen. If you omit the **CHOOSE=** *method-option*, then the selected model is the model at the final step in the selection process. The criteria that are supported depend on the type of model that is being fit. For the supported values of *criterion*, see the chapters for the relevant procedures.

COMPETITIVE

is applicable as a *method-option* only when **METHOD=STEPWISE**. If you specify the **COMPETITIVE** *method-option*, then the **SELECT=** criterion is evaluated for all models in which an effect currently in the model is dropped or an effect not yet in the model is added. The effect whose removal from or addition to the model yields the maximum improvement to the **SELECT=** criterion is dropped or added.

CRITERION=criterion

is an alias for the **SELECT=** *method-option*.

MAXEFFECTS=n

specifies the maximum number of effects in any model that is considered during the selection process. This *method-option* is ignored when you specify **METHOD=BACKWARD**. If, at some step of the selection process, the model contains the specified maximum number of effects, then no candidates for addition are considered.

MAXSTEPS=n

specifies the maximum number of selection steps to perform. The default value of *n* is the number of effects in the **MODEL** statement when **METHOD=FORWARD** or **METHOD=BACKWARD**. The default is three times the number of effects when **METHOD=STEPWISE**.

MINEFFECTS=*n*

specifies the minimum number of effects in any model that is considered during backward selection. This *method-option* is ignored unless METHOD=BACKWARD is specified. The backward selection process terminates if, at some step of the selection process, the model contains the specified minimum number of effects.

SELECT=*criterion*

specifies the criterion that the procedure uses to determine the order in which effects enter or leave at each step of the selection method. For each step, the effect whose addition to or removal from the current model yields the maximum improvement in the specified criterion is selected. For supported criteria, see the chapter for the relevant procedure.

STOP=NONE | *criterion*

specifies a criterion that is used to stop the selection process. The criteria that are supported depend on the type of model that is being fit. For information about the supported criteria, see the chapter for the relevant procedure.

If you omit this *method-option* but specify the **SELECT= *method-option***, then the criterion specified in the **SELECT= *method-option*** is also used as the criterion for the **STOP= *method-option***.

You can specify the following values:

NONE

stops the selection process if no suitable add or drop candidates can be found or if a size-based limit is reached. For example, if you specify STOP=NONE MAXEFFECTS=5, then the selection process stops at the first step that produces a model that has five effects.

criterion

stops the selection process if the selection process produces a local extremum of this *criterion* or if a size-based limit is reached. For example, if you specify STOP=AIC MAXSTEPS=5, then the selection process stops before step 5 if the sequence of models has a local minimum of the AIC criterion before step 5. The determination of whether a local minimum is reached is made on the basis of a stop horizon. The default stop horizon is 3, but you can change it by using the **STOPHORIZON=** option. If the stop horizon is *n* and the STOP=*criterion* at any step is better than the stop criterion at the next *n* steps, then the selection process terminates.

In addition, you can also specify the following *options*:

DETAILS=NONE | SUMMARY | ALL**DETAILS=STEPS<(CANDIDATES(ALL | *n*))>**

specifies the level of detail to be produced about the selection process. The default is DETAILS=SUMMARY.

The DETAILS=ALL and DETAILS=STEPS options produce the following output:

- tables that provide information about the model that is selected at each step of the selection process.
- entry and removal statistics for inclusion or exclusion candidates at each step. By default, only the top 10 candidates at each step are shown. If you specify STEPS(CANDIDATES(*n*)), then the

best n candidates are shown. If you specify STEPS(CANDIDATES(ALL)), then all candidates are shown.

- a selection summary table that shows by step the effect that is added to or removed from the model in addition to the values of the SELECT, STOP, and CHOOSE criteria for the resulting model.
- a stop reason table that describes why the selection process stopped.
- a selection reason table that describes why the selected model was chosen.
- a selected effects table that lists the effects that are in the selected model.

The DETAILS=SUMMARY option produces only the selection summary, stop reason, selection reason, and selected effects tables. In addition, for METHOD=ELASTICNET with neither a specified L2 value nor a solver specification, the DETAILS=SUMMARY option also displays an elastic net summary table, which shows the ridge regularization parameter L2 (in the ratio scaling) and CHOOSE criterion values in each L2 search step.

HIERARCHY=NONE | SINGLE | SINGLECLASS

specifies whether and how to apply the model hierarchy requirement. You can specify that only classification effects, or both classification and continuous effects, be subject to the hierarchy requirement. This option is ignored unless you also specify one of the following options: [METHOD=FORWARD](#), [METHOD=BACKWARD](#), or [METHOD=STEPWISE](#).

Model hierarchy refers to the requirement that, for any term to be in the model, all model effects that are contained in the term must be present in the model. For example, in order for the interaction A*B to enter the model, the main effects A and B must be in the model. Likewise, neither effect A nor effect B can leave the model while the interaction A*B is in the model.

You can specify the following values:

NONE	specifies that model hierarchy not be maintained. Any single effect can enter or leave the model at any step of the selection process.
SINGLE	specifies that only one effect enter or leave the model at one time, subject to the model hierarchy requirement. For example, suppose that the model contains the main effects A and B and the interaction A*B. In the first step of the selection process, either A or B can enter the model. In the second step, the other main effect can enter the model. The interaction effect can enter the model only when both main effects have already entered. Also, before A or B can be removed from the model, the A*B interaction must first be removed. All effects (CLASS and interval) are subject to the hierarchy requirement.
SINGLECLASS	is the same as HIERARCHY=SINGLE except that only CLASS effects are subject to the hierarchy requirement.

By default, HIERARCHY=NONE.

ORDERSELECT

specifies that effects in the selected model are displayed in the order in which they first entered the model. If you do not specify the ORDERSELECT option, then effects in the selected model are displayed in the order in which they appear in the SCALEMODEL or MODEL statement.

PLOT <(global-plot-options)> <= plot-request <(options)>>

PLOTS <(global-plot-options)> <= (plot-request <(options)> <...plot-request <(options)>>>

controls the selection process plots that are produced through ODS Graphics. The only procedure in this book that supports this option is the SEVSELECT procedure.

When you specify only one plot request, you can omit the parentheses around it. Here are some examples:

```
plots=all
plots=coefficients(unpack)
plots(unpack)=(coefficients criteria)
```

ODS Graphics must be enabled before you can request plots. For example:

```
ods graphics on;

proc sevselect;
  model y = x1-x100;
  selection method=forward plots=all;
run;

ods graphics off;
```

Global Plot Options

Each *global-plot-option* applies to all plots that the SELECTION statement generates, unless you alter the option by using a specific plot option that follows a *plot-request*. You can specify the following *global-plot-options*:

ENDSTEP=*n*

terminates the step ranges shown on the horizontal axes of plots at the specified step. By default, the step range that is shown terminates at the final step of the selection process.

MAXPARMLABEL=*n*

specifies the maximum number of characters beyond which all parameter labels on the coefficient progression panel and the coefficient progression plot are suppressed. By default, MAXPARMLABEL=20.

MAXSTEPLABEL=*n*

specifies the maximum number of characters of effect labels to display on the horizontal axes of the plots. By default, MAXSTEPLABEL=20. If the length of any effect label exceeds *n*, then step numbers are used on the horizontal axes of the plots.

STARTSTEP=*n*

specifies that the step ranges shown on the horizontal axes of plots start at the specified step. By default, the step range that is shown starts at the initial step of the selection process.

STEPAXIS=EFFECT | NUMBER

specifies the horizontal axis to be used on the plots, where this axis represents the sequence of entering or departing effects. You can specify the following values:

- | | |
|---------------|---|
| EFFECT | requests that each step be labeled by a prefix followed by the name of the effect that enters or leaves at that step. The prefix consists of the step number, followed by a “+” or a “-” sign, depending on whether the effect enters (+) or leaves (-) at that step. |
| NUMBER | requests that each step be labeled by the step number. |

UNPACK | UNPACKPANEL

suppresses paneling. By default, multiple plots can appear in the coefficient progression panel and the criteria panel. Specify UNPACK to see each plot individually. You can also specify UNPACK as a suboption of the CRITERIA and COEFFICIENTS options.

Specific Plot Options

You can specify the following *plot-requests* and their *options*:

ALL

produces all relevant plots.

COEFFICIENTS | COEFFICIENTPANEL <(UNPACK | UNPACKPANEL)>

creates a panel of two plots. The upper plot shows the progression of the parameter values as the selection process proceeds. The lower plot shows the progression of the CHOOSE= criterion. If no CHOOSE= criterion is in effect, then only the coefficient progression is shown. If you specify the UNPACK option, then the coefficient progression and the CHOOSE= criterion progression are shown in separate plots.

CRITERIA | CRITERIONPANEL <(UNPACK | UNPACKPANEL)>

creates a panel of model fit criteria. If you specify the UNPACK option, then each criterion progression is shown in a separate plot.

NONE

suppress all selection process plots, even if you specify other plot options.

SELECTION=method <(method-options)>

is an alias for the **METHOD=** option.

STOPHORIZON=n

specifies the number of consecutive steps at which the **STOP=** criterion must worsen in order for a local extremum to be detected. For example, suppose that **STOP=AIC** and the sequence of AIC values at steps 1 to 6 of a selection are 10, 7, 4, 6, 5, 2. If **STOPHORIZON=2**, then the AIC criterion is deemed to have a local minimum at step 3 because the AIC value at the next two steps are greater than the value 4 that occurs at step 3. However, if **STOPHORIZON=3**, then the value at step 3 is not deemed to be a local minimum because the AIC value at step 6 is lower than the AIC value at step 3. If you specify **STOP=NONE** then the stop horizon value is ignored. If you specify **STOP=SL**, then n is ignored and **STOPHORIZON=1** is used. By default, **STOPHORIZON=3** unless otherwise stated in individual procedure chapters.

Optimization Options

This section applies to the SEVSELECT procedure.

This section describes options that are typically available in the PROC statement or the NLOPTIONS statement of the procedures in this book that perform optimizations. The following notation is used to describe the options. $\boldsymbol{\beta}$ denotes the $p \times 1$ vector of parameters for the optimization and β_i is its i th element. The objective function being minimized, its $p \times 1$ gradient vector, and its $p \times p$ Hessian matrix are denoted as $f(\boldsymbol{\beta})$, $\mathbf{g}(\boldsymbol{\beta})$, and $\mathbf{H}(\boldsymbol{\beta})$, respectively. The gradient with respect to the i th parameter is denoted as $g_i(\boldsymbol{\beta})$. Superscripts in parentheses denote the iteration count; for example, $f(\boldsymbol{\beta})^{(k)}$ is the value of the objective function at iteration k .

ABSCONV=r

ABSTOL=r

specifies an absolute function convergence criterion. For minimization, termination requires $f(\boldsymbol{\beta})^{(k)} \leq r$, where $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $f(\cdot)$ is the objective function. The default value of r is the negative square root of the largest double-precision value, which serves only as a protection against overflows.

ABSFCNV=r

ABSFTOL=r

specifies an absolute function difference convergence criterion. For all techniques except NMSIMP, termination requires a small change of the function value in successive iterations:

$$|f(\boldsymbol{\beta}^{(k-1)}) - f(\boldsymbol{\beta}^{(k)})| \leq r$$

Here, $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\beta}^{(k)}$ is defined as the vertex that has the lowest function value and $\boldsymbol{\beta}^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex. By default, **ABSFCNV=0**.

ABSGCONV= r **ABSGTOL= r**

specifies an absolute gradient convergence criterion. Termination requires the maximum absolute gradient element to be small:

$$\max_j |g_j(\boldsymbol{\beta}^{(k)})| \leq r$$

Here, $\boldsymbol{\beta}$ is the vector of parameters in the optimization and $g_j(\cdot)$ is the gradient of the objective function with respect to the j th parameter. This criterion is not used by the NMSIMP technique. By default, ABSGCONV=1E-5.

ABSXCONV= r **ABSXTOL= r**

specifies an absolute parameter convergence criterion: For all techniques except NMSIMP, termination requires a small Euclidean distance between successive parameter vectors,

$$\|\boldsymbol{\beta}^{(k)} - \boldsymbol{\beta}^{(k-1)}\|_2 \leq r$$

For the NMSIMP technique, termination requires either a small length $\alpha^{(k)}$ of the vertices of a restart simplex,

$$\alpha^{(k)} \leq r$$

or a small simplex size,

$$\delta^{(k)} \leq r$$

where the simplex size $\delta^{(k)}$ is defined as the L1 distance from the simplex vertex $\boldsymbol{\xi}^{(k)}$ that has the smallest function value to the other p simplex points $\boldsymbol{\beta}_l^{(k)} \neq \boldsymbol{\xi}^{(k)}$:

$$\delta^{(k)} = \sum_{\boldsymbol{\beta}_l \neq \boldsymbol{\xi}} \|\boldsymbol{\beta}_l^{(k)} - \boldsymbol{\xi}^{(k)}\|_1$$

The default is $r = 1\text{E}-8$ for the NMSIMP technique and $r = 0$ otherwise.

FCONV= r **FTOL= r**

specifies a relative function difference convergence criterion. For all techniques except NMSIMP, termination requires a small relative change of the function value in successive iterations,

$$\frac{|f(\boldsymbol{\beta}^{(k)}) - f(\boldsymbol{\beta}^{(k-1)})|}{\max(|f(\boldsymbol{\beta}^{(k-1)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the **FSIZE=** option. Here, $\boldsymbol{\beta}$ denotes the vector of parameters that participate in the optimization, and $f(\cdot)$ is the objective function. The same formula is used for the NMSIMP technique, but $\boldsymbol{\beta}^{(k)}$ is defined as the vertex that has the lowest function value and $\boldsymbol{\beta}^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex.

The default value is $r=2 \times \epsilon$ where ϵ is the machine precision, which is the smallest double-precision floating-point number such that $1 + \epsilon > 1$.

FCONV2=r**FTOL2=r**

specifies a second function convergence criterion. For all techniques except NMSIMP, termination requires a small predicted reduction of the objective function:

$$df^{(k)} \approx f(\boldsymbol{\beta}^{(k)}) - f(\boldsymbol{\beta}^{(k)} + \mathbf{s}^{(k)})$$

The predicted reduction

$$\begin{aligned} df^{(k)} &= -\mathbf{g}^{(k)'} \mathbf{s}^{(k)} - \frac{1}{2} \mathbf{s}^{(k)'} \mathbf{H}^{(k)} \mathbf{s}^{(k)} \\ &= -\frac{1}{2} \mathbf{s}^{(k)'} \mathbf{g}^{(k)} \leq r \end{aligned}$$

is computed by approximating the objective function f by the first two terms of the Taylor series and substituting the Newton step,

$$\mathbf{s}^{(k)} = -[\mathbf{H}^{(k)}]^{-1} \mathbf{g}^{(k)}$$

For the NMSIMP technique, termination requires a small standard deviation of the function values of the $p + 1$ simplex vertices $\boldsymbol{\beta}_l^{(k)}$, $l = 0, \dots, p$,

$$\sqrt{\frac{1}{n+1} \sum_l \left[f(\boldsymbol{\beta}_l^{(k)}) - \bar{f}(\boldsymbol{\beta}^{(k)}) \right]^2} \leq r$$

where $\bar{f}(\boldsymbol{\beta}^{(k)}) = \frac{1}{p+1} \sum_l f(\boldsymbol{\beta}_l^{(k)})$. If there are p_{act} boundary constraints active at $\boldsymbol{\beta}^{(k)}$, the mean and standard deviation are computed only for the $n + 1 - p_{act}$ unconstrained vertices.

The default value is $r = 1\text{E-}6$ for the NMSIMP technique and $r = 0$ otherwise.

FSIZE=r

specifies the FSIZE parameter of the relative function and relative gradient termination criteria. The default value is $r = 0$. For more information, see the FCONV= and GCONV= options.

GCONV=r**GTOL=r**

specifies a relative gradient convergence criterion. For all techniques except CONGRA and NMSIMP, termination requires that the normalized predicted function reduction be small:

$$\frac{\mathbf{g}(\boldsymbol{\beta}^{(k)})' [\mathbf{H}^{(k)}]^{-1} \mathbf{g}(\boldsymbol{\beta}^{(k)})}{\max(|f(\boldsymbol{\beta}^{(k)})|, \text{FSIZE})} \leq r$$

where FSIZE is defined by the FSIZE= option. Here, $\boldsymbol{\beta}$ denotes the vector of parameters that participate in the optimization, $f(\cdot)$ is the objective function, and $\mathbf{g}(\cdot)$ is the gradient. For the CONGRA technique (where a reliable Hessian estimate $\mathbf{H}$ is not available), the following criterion is used:

$$\frac{\|\mathbf{g}(\boldsymbol{\beta}^{(k)})\|_2 \|\mathbf{s}(\boldsymbol{\beta}^{(k)})\|_2}{\|\mathbf{g}(\boldsymbol{\beta}^{(k)}) - \mathbf{g}(\boldsymbol{\beta}^{(k-1)})\|_2 \max(|f(\boldsymbol{\beta}^{(k)})|, \text{FSIZE})} \leq r$$

This criterion is not used by the NMSIMP technique. By default, GCONV=1E-8.

GCONV2=*r***GTOL2=*r***

specifies another relative gradient convergence criterion. For the TRUREG, NRRIDG, and NEWRAP techniques, the following criterion of Browne (1982) is used:

$$\max_j \frac{|\mathbf{g}_j(\boldsymbol{\beta}^{(k)})|}{\sqrt{f(\boldsymbol{\beta}^{(k)})\mathbf{H}_{j,j}^{(k)}}} \leq r$$

This criterion is not used by the other techniques.

By default, GCONV2=0.

MAXFUNC=*n***MAXFU=*n***

specifies the maximum number *n* of function calls in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 125
- QUANEW and DBLDOG: 500
- CONGRA: 1,000
- NMSIMP: 3,000

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually performed can exceed the number that is specified by this option. You can specify the optimization technique in the **TECHNIQUE=** option.

MAXITER=*n***MAXIT=*n***

specifies the maximum number *n* of iterations in the optimization process. The default values are as follows, depending on the optimization technique:

- TRUREG, NRRIDG, and NEWRAP: 50
- QUANEW and DBLDOG: 200
- CONGRA: 400
- NMSIMP: 1,000

These default values also apply when *n* is specified as a missing value. You can specify the optimization technique in the **TECHNIQUE=** option.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The time specified by *r* is checked only once at the end of each iteration. Therefore, the actual running time can be longer than *r*. The default value is the largest floating-point double representation of your computer.

MINITER=*n***MINIT**=*n*

specifies the minimum number of iterations. If you request more iterations than are actually needed for convergence to a stationary point, the optimization algorithms can behave strangely. For example, the effect of rounding errors can prevent the algorithm from continuing for the required number of iterations. By default, MINITER=0.

TECHNIQUE=*technique***TECH**=*technique*

specifies the optimization technique for obtaining maximum likelihood estimates. You can specify one of the following *techniques*:

CONGRA	performs a conjugate-gradient optimization.
DBLDOG	performs a version of double-dogleg optimization.
NEWRAP	performs a Newton-Raphson optimization with line search.
NMSIMP	performs a Nelder-Mead simplex optimization.
NONE	performs no optimization.
NRRIDG	performs a Newton-Raphson optimization with ridging.
QUANEW	performs a dual quasi-Newton optimization.
TRUREG	performs a trust-region optimization

The default method varies by the procedure. For the SEVSELECT procedure, the default is TECHNIQUE=TRUREG.

For more information, see the section “[Choosing an Optimization Algorithm](#)” on page 108.

XCONV=*r***XTOL**=*r*

specifies the relative parameter convergence criterion. Convergence requires a small relative parameter change in subsequent iterations,

$$\frac{\max_j |\beta_j^{(k)} - \beta_j^{(k-1)}|}{\max(|\beta_j^{(k)}|, |\beta_j^{(k-1)}|, \text{XSIZE})} \leq r$$

where XSIZE is defined by the **XSIZE**= option. and $\beta_j^{(i)}$ is the estimate of the *j*th parameter at iteration *i*. For the NMSIMP technique, the same formula is used, but $\beta_j^{(k)}$ is defined as the vertex that has the lowest function value and $\beta_j^{(k-1)}$ is defined as the vertex that has the highest function value in the simplex. The default value is $r = 1\text{E}-8$ for the NMSIMP technique and $r = 0$ otherwise.

XSIZE=*r*

specifies the XSIZE parameter of the relative parameter termination criterion. The value of *r* must be greater than or equal to 0; the default is $r = 0$. For more information, see the XCONV= option.

Details for SAS Econometrics Procedures

Levelization of Classification Variables

This section applies to the following procedures: CNTSELECT, CPANEL, CQLIM, CSPATIALREG, and SEVSELECT.

A classification variable enters the statistical analysis or model not through its values but through its levels. The process of associating values of a variable with levels is called *levelization*.

During the process of levelization, observations that share the same value are assigned to the same level. The manner in which values are grouped can be affected by the inclusion of formats. The sort order of the levels can be determined by specifying the ORDER= option in the procedure statement. In procedures in this book, you can also control the sorting order separately for each variable in the CLASS statement.

Consider the data on nine observations in Table 4.7. The variable A is integer-valued, and the variable X is a continuous variable that has a missing value for the fourth observation. The fourth and fifth columns of Table 4.7 apply two different formats to the variable X.

Table 4.7 Example Data for Levelization

Obs	A	x	FORMAT x 3.0	FORMAT x 3.1
1	2	1.09	1	1.1
2	2	1.13	1	1.1
3	2	1.27	1	1.3
4	3	.	.	.
5	3	2.26	2	2.3
6	3	2.48	2	2.5
7	4	3.34	3	3.3
8	4	3.34	3	3.3
9	4	3.14	3	3.1

By default, levelization of the variables groups the observations by the formatted value of the variable, except for numerical variables for which no explicit format is provided. Numerical variables for which no explicit format is provided are sorted by their internal value. The levelization of the four columns in Table 4.7 leads to the level assignment in Table 4.8.

Table 4.8 Values and Levels

Obs	A		X		FORMAT x 3.0		FORMAT x 3.1	
	Value	Level	Value	Level	Value	Level	Value	Level
1	2	1	1.09	1	1	1	1.1	1

Table 4.8 *continued*

Obs	A		X		FORMAT x 3.0		FORMAT x 3.1	
	Value	Level	Value	Level	Value	Level	Value	Level
2	2	1	1.13	2	1	1	1.1	1
3	2	1	1.27	3	1	1	1.3	2
4	3	2	.	.	.	.	.	.
5	3	2	2.26	4	2	2	2.3	3
6	3	2	2.48	5	2	2	2.5	4
7	4	3	3.34	7	3	3	3.3	6
8	4	3	3.34	7	3	3	3.3	6
9	4	3	3.14	6	3	3	3.1	5

The sort order for the levels of CLASS variables can be specified in the **ORDER=** option in the **CLASS** statement.

When **ORDER=FORMATTED** (which is the default) is in effect for numeric variables for which you have supplied no explicit format, the levels are ordered by their internal values. To order numeric classification levels that have no explicit format by their BEST12. formatted values, you can specify the BEST12. format explicitly for the CLASS variables.

Table 4.9 shows how values of the **ORDER=** option are interpreted.

Table 4.9 Interpretation of Values of **ORDER=** Option

Value of ORDER=	Levels Sorted By
FORMATTED	External formatted value, except for numeric variables that have no explicit format, which are sorted by their unformatted (internal) value. The sort order is machine-dependent.
FREQ	Descending frequency count (levels that have the most observations come first in the order)
INTERNAL	Unformatted value. The sort order is machine-dependent.

For more information about sort order, see the chapter about the SORT procedure in the *Base SAS Procedures Guide* and the discussion of BY-group processing in the “Grouping Data” section of *SAS Programmers Guide: Essentials*.

When the **MISSING** option is specified in the **CLASS** statement, the missing values (‘.’ for a numeric variable and blanks for a character variable) are included in the levelization and are assigned a level. Table 4.10 displays the results of levelizing the values in Table 4.7 when the **MISSING** option is in effect.

Table 4.10 Values and Levels When the MISSING Option Is Specified

Obs	A		X		FORMAT x 3.0		FORMAT x 3.1	
	Value	Level	Value	Level	Value	Level	Value	Level
1	2	1	1.09	2	1	2	1.1	2
2	2	1	1.13	3	1	2	1.1	2
3	2	1	1.27	4	1	2	1.3	3
4	3	2	.	1	.	1	.	1
5	3	2	2.26	5	2	3	2.3	4
6	3	2	2.48	6	2	3	2.5	5
7	4	3	3.34	8	3	4	3.3	7
8	4	3	3.34	8	3	4	3.3	7
9	4	3	3.14	7	3	4	3.1	6

When the MISSING option is not specified, it is important to understand the implications of missing values for your statistical analysis. When a procedure in this book levelizes the CLASS variables, an observation for which any CLASS variable has a missing value is excluded from the analysis.

Procedures in this book print a “Number of Observations” table that shows the number of observations that are read from the data set and the number of observations that are used in the analysis. Pay careful attention to this table—especially when your data table contains missing values—to ensure that no observations are unintentionally excluded from the analysis.

Specification and Parameterization of Model Effects

This section applies to the following procedures: CNTSELECT, CPANEL, CQLIM, CSPATIALREG, HMM, and SEVSELECT.

Procedures in this book that have a MODEL or SCALEMODEL statement support the formation of effects. An *effect* is an element in a linear model structure that is formed from one or more variables. At some point the statistical representations of these models involve linear structures such as

$$\mathbf{X}\boldsymbol{\beta}$$

or

$$\mathbf{X}\boldsymbol{\beta} + \mathbf{Z}\boldsymbol{\gamma}$$

The model matrices $\mathbf{X}$ and $\mathbf{Z}$ are formed according to effect-construction rules.

Procedures that also have a CLASS statement support the rich set of effects that is discussed in this section.

Procedures that also have an EFFECT statement enable you to construct special *constructed* effects that are discussed in “EFFECT Statement” on page 62.

In order to correctly interpret the results from a statistical analysis, you need to understand how construction (*parameterization*) rules apply to regression-type models, whether these are scale regression models as in the SEVSELECT procedure or count regression models as in the CNTSELECT procedures.

Effects are specified by a special notation that uses variable names and operators. There are two types of variables: classification (or CLASS) variables and continuous variables. *Classification variables* can be either numeric or character and are specified in a CLASS statement. For more information, see the section “[Levelization of Classification Variables](#)” on page 89. An independent variable that is not declared in the CLASS statement is assumed to be *continuous*. For example, the heights and weights of subjects are continuous variables.

Two primary operators (crossing and nesting) are used for combining the variables, and several additional operators are used to simplify effect specification. Operators are discussed in the section “[Effect Operators](#)” on page 92.

Procedures in this book that have a CLASS statement support a general linear model (GLM) parameterization and might also support nonsingular parameterizations for the classification variables. The GLM parameterization, commonly called *dummy* parameterization, is the default for all procedures in this book. For more information, see the sections “[GLM Parameterization of Classification Variables and Effects](#)” on page 94 and “[Nonsingular Parameterization](#)” on page 99.

NOTE: This section uses the MODEL statement in all examples for illustration purposes. All discussion also applies to the SCALEMODEL statement in the SEVSELECT procedure (where you specify only the regression effects) and to other types of model specification statements in other procedures (such as the ZEROMODEL statement in the CNTSELECT procedure).

Effect Operators

Table 4.11 summarizes the operators that are available for selecting and constructing effects. These operators are discussed in the following sections.

Table 4.11 Available Effect Operators

Operator	Example	Description
Interaction	A*B	Crosses the levels of the effects
Nesting	A(B)	Nests A levels within B levels
Bar operator	A B C	Specifies all interactions
At sign operator	A B C@2	Reduces interactions in bar effects
Dash operator	A1-A10	Specifies sequentially numbered variables
Colon operator	A:	Specifies variables with common prefix
Double dash operator	A- -C	Specifies sequential variables in data set order

Bar and At Sign Operators

You can shorten the specification of a large factorial model by using the bar operator. For example, two ways of writing the model for a full three-way factorial model follow:

```
model Y = A B C A*B A*C B*C A*B*C;
```

```
model Y = A|B|C;
```

When the bar (|) is used, the right and left sides become effects, and the cross of them becomes an effect. Multiple bars are permitted. The expressions are expanded from left to right, using rules 2–4 in Searle (1971, p. 390).

- Multiple bars are evaluated from left to right. For example, $A | B | C$ is evaluated as follows:

$$\begin{aligned} A | B | C &\rightarrow \{ A | B \} | C \\ &\rightarrow \{ A B A*B \} | C \\ &\rightarrow A B A*B C A*C B*C A*B*C \end{aligned}$$

- Crossed and nested groups of variables are combined. For example, $A(B) | C(D)$ generates $A*C(B D)$, among other terms.
- Duplicate variables are removed. For example, $A(C) | B(C)$ generates $A*B(C C)$, among other terms, and the extra C is removed.
- Effects are discarded if a variable occurs on both the crossed and nested parts of an effect. For example, $A(B) | B(D E)$ generates $A*B(B D E)$, but this effect is eliminated immediately.

You can also specify the maximum number of variables involved in any effect that results from bar evaluation by specifying that maximum number, preceded by an at sign (@), at the end of the bar effect. For example, the following specification selects only those effects that contain two or fewer variables:

```
model Y = A|B|C@2;
```

The preceding example is equivalent to specifying the following MODEL statement:

```
model Y = A B C A*B A*C B*C;
```

More examples of using the bar and at operators follow:

$A C(B)$	is equivalent to	$A C(B) A*C(B)$
$A(B) C(B)$	is equivalent to	$A(B) C(B) A*C(B)$
$A(B) B(D E)$	is equivalent to	$A(B) B(D E)$
$A B(A) C$	is equivalent to	$A B(A) C A*C B*C(A)$
$A B(A) C@2$	is equivalent to	$A B(A) C A*C$
$A B C D@2$	is equivalent to	$A B A*B C A*C B*C D A*D B*D C*D$
$A*B(C*D)$	is equivalent to	$A*B(C D)$

Colon, Dash, and Double Dash Operators

You can simplify the specification of a large model when some of your variables have a common prefix by using the colon (:) operator and the dash (-) operator. The dash operator enables you to list variables that are numbered sequentially, and the colon operator selects all variables with a given prefix. For example, if your data set contains the variables X1 through X9, the following MODEL statements are equivalent:

```
model Y = X1 X2 X3 X4 X5 X6 X7 X8 X9;
```

```
model Y = X1-X9;
```

```
model Y = X:;
```

If your data set contains only the three covariates X1, X2, and X9, then the colon operator selects all three variables:

```
model Y = X:;
```

However, the following specification returns an error because X3 through X8 are not in the data set:

```
model Y = X1-X9;
```

The double dash (- -) operator enables you to select variables that are stored sequentially in the SAS data set, whether or not they have a common prefix. You can use the CONTENTS procedure (see [Base SAS Procedures Guide](#)) to determine your variable ordering. For example, if you replace the dash in the preceding MODEL statement with a double dash, as follows, then all three variables are selected:

```
model Y = X1--X9;
```

If your data set contains the variables A, B, and C, then you can use the double dash operator to select these variables by specifying the following:

```
model Y = A--C;
```

GLM Parameterization of Classification Variables and Effects

Table 4.12 shows the types of effects that are available in procedures in this book; they are discussed in more detail in the following subsections. Let A, B, and C represent classification variables, and let X and Z represent continuous variables.

Table 4.12 Available Types of Effects

Effect	Example	Description
Intercept	Default	Intercept (unless the NOINT option is specified)
Regression	X Z	Continuous variables
Polynomial	X*Z	Interaction of continuous variables
Main	A B	CLASS variables
Interaction	A*B	Crossing of CLASS variables
Nested	A(B)	Main effect A nested within CLASS effect B
Continuous-by-class	X*A	Crossing of continuous and CLASS variables
Continuous-nesting-class	X(A)	Continuous variable X1 nested within CLASS variable A
General	X*Z*A(B)	Combinations of different types of effects

Table 4.13 shows some examples of MODEL statements that use various types of effects.

Table 4.13 MODEL Statement Effect Examples

Specification	Type of Model
<code>model Y=X;</code>	Simple regression
<code>model Y=X Z;</code>	Multiple regression
<code>model Y=X X*X;</code>	Polynomial regression
<code>model Y=A;</code>	One-way analysis of variance (ANOVA)
<code>model Y=A B C;</code>	Main-effects ANOVA
<code>model Y=A B A*B;</code>	Factorial ANOVA with interaction
<code>model y=A B (A) C (B A) ;</code>	Nested ANOVA
<code>model Y=A X;</code>	Analysis of covariance (ANCOVA)
<code>model Y=A X (A) ;</code>	Separate-slopes regression
<code>model Y=A X X*A;</code>	Homogeneity-of-slopes regression

Intercept

By default, linear models that are created by procedures in this book automatically include a column of 1s in **X**. This column corresponds to an intercept parameter. In many procedures, you can use the **NOINT** option in the MODEL statement to suppress this intercept. For example, the **NOINT** option is useful when the MODEL statement contains a classification effect and you want the parameter estimates to be in terms of the mean response for each level of that effect.

Regression Effects

Numeric variables or polynomial terms that involve them can be included in the model as regression effects (covariates). The actual values of such terms are included as columns of the relevant model matrices. You can use the **bar operator** along with a regression effect to generate polynomial effects. For example, $X \mid X \mid X$ expands to $X \ X^2 \ X^3$, which is a cubic model.

Main Effects

If a classification variable has m levels, the GLM parameterization generates m columns for its main effect in the model matrix. Each column is an indicator variable for a particular level. The order of the columns is the sort order of the values of their levels and can be controlled by the **ORDER=** option in the **CLASS** statement.

Table 4.14 is an example where β_0 denotes the intercept and A and B are classification variables that have two and three levels, respectively.

Table 4.14 Example of Main Effects

Data		I	A		B		
A	B	β_0	A1	A2	B1	B2	B3
1	1	1	1	0	1	0	0
1	2	1	1	0	0	1	0
1	3	1	1	0	0	0	1
2	1	1	0	1	1	0	0

Table 4.14 *continued*

Data		I	A		B		
2	2	1	0	1	0	1	0
2	3	1	0	1	0	0	1

There are usually more columns for these effects than there are degrees of freedom to estimate them. In other words, the GLM parameterization of main effects is *singular*.

Interaction Effects

Often a model includes interaction (crossed) effects to account for how the effect of a variable changes along with the values of other variables. With an interaction, the terms are first reordered to correspond to the order of the variables in the **CLASS** statement. Thus, B*A becomes A*B if A precedes B in the **CLASS** statement. Then, the GLM parameterization generates columns for all combinations of levels that occur in the data. The order of the columns is such that the rightmost variables in the interaction change faster than the leftmost variables (Table 4.15).

Table 4.15 Example of Interaction Effects

Data		I	A		B			A*B					
A	B	β_0	A1	A2	B1	B2	B3	A1B1	A1B2	A1B3	A2B1	A2B2	A2B3
1	1	1	1	0	1	0	0	1	0	0	0	0	0
1	2	1	1	0	0	1	0	0	1	0	0	0	0
1	3	1	1	0	0	0	1	0	0	1	0	0	0
2	1	1	0	1	1	0	0	0	0	0	1	0	0
2	2	1	0	1	0	1	0	0	0	0	0	1	0
2	3	1	0	1	0	0	1	0	0	0	0	0	1

In the preceding matrix, main-effects columns are not linearly independent of crossed-effects columns. In fact, the column space for the crossed effects contains the space of the main effect.

When your model contains many interaction effects, you might be able to code them more parsimoniously by using the **bar operator** (**|**). The bar operator generates all possible interaction effects. For example, A | B | C expands to A B A*B C A*C B*C A*B*C. To eliminate higher-order interaction effects, use the **at sign** (**@**) in conjunction with the bar operator. For example, A | B | C | D@2 expands to A B A*B C A*C B*C D A*D B*D C*D.

Nested Effects

Nested effects are generated in the same manner as crossed effects. Hence, the design columns that are generated by the following two statements are the same (but the ordering of the columns is different):

```
model Y=A B(A) ;
```

```
model Y=A A*B;
```

The nesting operator in procedures in this book is more of a notational convenience than an operation that is distinct from crossing. Nested effects are typically characterized by the property that the nested variables do not appear as main effects. The order of the variables within nesting parentheses is made to correspond to the

order of these variables in the **CLASS** statement. The order of the columns is such that variables outside the parentheses index faster than those inside the parentheses, and the rightmost nested variables index faster than the leftmost variables (Table 4.16).

Table 4.16 Example of Nested Effects

Data		I	A		B(A)					
A	B	β_0	A1	A2	B1A1	B2A1	B3A1	B1A2	B2A2	B3A2
1	1	1	1	0	1	0	0	0	0	0
1	2	1	1	0	0	1	0	0	0	0
1	3	1	1	0	0	0	1	0	0	0
2	1	1	0	1	0	0	0	1	0	0
2	2	1	0	1	0	0	0	0	1	0
2	3	1	0	1	0	0	0	0	0	1

Continuous-Nesting-Class Effects

When a continuous variable nests or crosses with a classification variable, the design columns are constructed by multiplying the continuous values into the design columns for the classification effect (Table 4.17).

Table 4.17 Example of Continuous-Nesting-Class Effects

Data		I	A		X(A)	
X	A	β_0	A1	A2	X(A1)	X(A2)
21	1	1	1	0	21	0
24	1	1	1	0	24	0
22	1	1	1	0	22	0
28	2	1	0	1	0	28
19	2	1	0	1	0	19
23	2	1	0	1	0	23

This model estimates a separate intercept and a separate slope for X within each level of A.

Continuous-by-Class Effects

Continuous-by-class effects generate the same design columns as continuous-nesting-class effects. Table 4.18 shows the construction of the X*A effect. The two columns for this effect are the same as the columns for the X(A) effect in Table 4.17.

Table 4.18 Example of Continuous-by-Class Effects

Data		I	X	A		X*A	
X	A	β_0	X	A1	A2	X*A1	X*A2
21	1	1	21	1	0	21	0
24	1	1	24	1	0	24	0
22	1	1	22	1	0	22	0

Table 4.18 *continued*

Data		I	X	A		X*A	
28	2	1	28	0	1	0	28
19	2	1	19	0	1	0	19
23	2	1	23	0	1	0	23

You can use continuous-by-class effects together with pure continuous effects to test for homogeneity of slopes.

General Effects

An example that combines all the effects is $X1*X2*A*B*C(D\ E)$. The continuous list comes first, followed by the crossed list, followed by the nested list in parentheses.

Effects might be renamed by the procedure to correspond to ordering rules. For example, $B*A(E\ D)$ might be renamed $A*B(D\ E)$ to satisfy the following:

- Classification variables that occur outside parentheses (crossed effects) are sorted in the order in which they appear in the CLASS statement.
- Variables within parentheses (nested effects) are sorted in the order in which they appear in the CLASS statement.

The sequencing of the parameters that are generated by an effect is determined by the variables whose levels are indexed faster:

- Variables in the crossed list index faster than variables in the nested list.
- Within a crossed or nested list, variables to the right index faster than variables to the left.

For example, suppose that a model includes four effects—A, B, C, and D—each having two levels, 1 and 2, and that the CLASS statement is as follows:

```
class A B C D;
```

Then the order of the parameters for the effect $B*A(C\ D)$, which is renamed $A*B(C\ D)$, is as follows:

$$\begin{aligned}
 &A_1B_1C_1D_1 \rightarrow A_1B_2C_1D_1 \rightarrow A_2B_1C_1D_1 \rightarrow A_2B_2C_1D_1 \rightarrow \\
 &A_1B_1C_1D_2 \rightarrow A_1B_2C_1D_2 \rightarrow A_2B_1C_1D_2 \rightarrow A_2B_2C_1D_2 \rightarrow \\
 &A_1B_1C_2D_1 \rightarrow A_1B_2C_2D_1 \rightarrow A_2B_1C_2D_1 \rightarrow A_2B_2C_2D_1 \rightarrow \\
 &A_1B_1C_2D_2 \rightarrow A_1B_2C_2D_2 \rightarrow A_2B_1C_2D_2 \rightarrow A_2B_2C_2D_2
 \end{aligned}$$

Note that first the crossed effects B and A are sorted in the order in which they appear in the CLASS statement so that A precedes B in the parameter list. Then, for each combination of the nested effects in turn, combinations of A and B appear. The B effect changes fastest because it is rightmost in the cross list. Then A changes next fastest, and D changes next fastest. The C effect changes most slowly because it is leftmost in the nested list.

Nonsingular Parameterization

When a parameterization of main effects provides the same number of columns for the effects as there are degrees of freedom to estimate them, the parameterization is called *nonsingular*. A variety of nonsingular parameterizations for classification effects are available for many procedures in this book. In most of these procedures you use the `PARAM=` option in the `CLASS` statement to specify the parameterization.

Consider a model with one `CLASS` variable `A` that has four levels, 1, 2, 5, and 7. Details of the possible choices for the `PARAM=` option follow.

REFERENCE

Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of 0. For example, if the reference level is 7 (`REF=7`), the design matrix columns for `A` are as follows.

Reference Coding			
A	Design Matrix		
	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	0	0	0

Parameter estimates of `CLASS` main effects that use the reference coding scheme estimate the difference in the effect of each nonreference level compared to the effect of the reference level.

EFFECT

Three columns are created to indicate group membership of the nonreference levels. For the reference level, all three dummy variables have a value of -1 . For example, if the reference level is 7 (`REF=7`), the design matrix columns for `A` are as follows.

Effect Coding			
A	Design Matrix		
	A1	A2	A5
1	1	0	0
2	0	1	0
5	0	0	1
7	-1	-1	-1

Parameter estimates of `CLASS` main effects that use the effect coding scheme estimate the difference in the effect of each nonreference level compared to the average effect over all four levels.

ORDINAL | THERMOMETER

Three columns are created to indicate group membership of the higher levels of the effect. For the first level of the effect (which for `A` is 1), all three dummy variables have a value of 0. The design matrix columns for `A` are as follows.

Ordinal Coding			
A	Design Matrix		
	A2	A5	A7
1	0	0	0
2	1	0	0
5	1	1	0
7	1	1	1

The first level of the effect is a control or baseline level. Parameter estimates of CLASS main effects, using the ORDINAL coding scheme, estimate the differences between effects of successive levels. When the parameters have the same sign, the effect is monotonic across the levels.

POLYNOMIAL | POLY Three columns are created. The first represents the linear term (x), the second represents the quadratic term (x^2), and the third represents the cubic term (x^3), where x is the level value. If the CLASS levels are not numeric, they are translated into 1, 2, 3, ... according to their sort order. The design matrix columns for A are as follows.

Polynomial Coding			
A	Design Matrix		
	APOLY1	APOLY2	APOLY3
1	1	1	1
2	2	4	8
5	5	25	125
7	7	49	343

ORTHEFFECT The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=EFFECT. The design matrix columns for A are as follows.

Orthogonal Effect Coding			
A	Design Matrix		
	AOEFF1	AOEFF2	AOEFF3
1	1.41421	-0.81650	-0.57735
2	0	1.63299	-0.57735
5	0	0	1.73205
7	-1.41421	-0.81649	-0.57735

ORTHORDINAL | ORTHOTHERM The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=ORDINAL. The design matrix columns for A are as follows.

Orthogonal Ordinal Coding			
Design Matrix			
A	AOORD1	AOORD2	AOORD3
1	-1.73205	0	0
2	0.57735	-1.63299	0
5	0.57735	0.81650	-1.41421
7	0.57735	0.81650	1.41421

ORTHPOLY

The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=POLY. The design matrix columns for A are as follows.

Orthogonal Polynomial Coding			
Design Matrix			
A	AOPOLY1	AOPOLY2	AOPOLY5
1	-1.15311	0.90712	-0.92058
2	-0.73380	-0.54041	1.47292
5	0.52414	-1.37034	-0.92058
7	1.36277	1.00363	0.36823

ORTHREF

The columns are obtained by applying the Gram-Schmidt orthogonalization to the columns for PARAM=REFERENCE. The design matrix columns for A are as follows.

Orthogonal Reference Coding			
Design Matrix			
A	AOREF1	AOREF2	AOREF3
1	1.73205	0	0
2	-0.57735	1.63299	0
5	-0.57735	-0.81650	1.41421
7	-0.57735	-0.81650	-1.41421

Class Variable Parameterization with Unbalanced Designs

Procedures in this book initially parameterize the CLASS variables by looking at the levels of the variables across the complete data set. If you have an *unbalanced* replication of levels across variables or BY groups, then the design matrix and the parameter interpretation might be different from what you expect. For example, suppose you have a model that has one CLASS variable A with three levels (1, 2, and 3), and another CLASS variable B with two levels (1 and 2). If the third level of A occurs only with the first level of B, if you use the EFFECT parameterization, and if your model contains the effect A(B) and an intercept, then the design for A within the second level of B is not a differential effect. In particular, the design looks like the following:

		Design Matrix			
B	A	A(B=1)		A(B=2)	
		A1	A2	A1	A2
1	1	1	0	0	0
1	2	0	1	0	0
1	3	-1	-1	0	0
2	1	0	0	1	0
2	2	0	0	0	1

Procedures in this book detect linear dependency among the last two design variables and set the parameter for A2(B=2) to 0, resulting in an interpretation of these parameters as if they were reference- or dummy-coded. The REFERENCE or GLM parameterization might be more appropriate for such problems.

Model Selection Methods

The model selection methods are specified in the **METHOD=** option in the **SELECTION** statement. The following methods are available, although specific procedures might support only a subset of these methods. Furthermore, the examples in this section refer to fit criteria that might not be supported by a specific procedure.

Forward Selection

This section applies to the following procedures: CNTSELECT and SEVSELECT.

METHOD=FORWARD specifies the forward selection technique, which begins with just the intercept and then sequentially adds the effect that most improves the fit. The process terminates when no significant improvement can be obtained by adding any effect.

In the traditional implementation of forward selection, the statistic that is used to determine whether to add an effect is the significance level of a hypothesis test that reflects an effect's contribution to the model if it is included. At each step, the effect that is most significant is added. The process stops when the significance level for adding any effect is greater than some specified entry significance level.

An alternative approach to address the critical problem of when to stop the selection process that is implemented by the procedures in this book is to assess the quality of the models that are produced by the forward selection method and choose the model from this sequence that “best” balances goodness of fit against model complexity. You can use several criteria for this purpose. These criteria fall into two groups—information criteria and criteria that are based on out-of-sample prediction performance.

It is important to keep in mind that forward selection bases the decision about what effect to add at any step by considering models that differ by one effect from the current model. This search paradigm cannot guarantee reaching a “best” subset model. Furthermore, the add decision is greedy in the sense that the effect that is deemed most significant is the effect that is added. The optimality of this one step choice depends on the optimality of the selection criterion for the model that contains that effect. You can specify the criterion to optimize at each step by using the **SELECT=** option. For example, the following statement requests that at each step the effect that is added be the one that produces a model that has the smallest value of the SBC:

```
selection method=forward(select=SBC);
```

When all effects are variables (that is, effects have one degree of freedom and no hierarchy), using AIC, AICC, or SBC as the selection criterion for forward selection produces the same sequence of additions. However, if the degrees of freedom contributed by different effects are not constant or if an out-of-sample prediction-based criterion is used, then different sequences of additions might be obtained.

If you specify only the **SELECT=** criterion, then this criterion is also used to decide when to stop the selection process. In the previous example, not only do effects enter based on the SBC value, but the selection terminates when SBC has a local minimum.

You use the **CHOOSE=** option to specify the criterion for selecting one model from the sequence of models produced. If you do not specify a **CHOOSE=** criterion, then the model at the final step is the selected model.

For example, if you specify the following statement, then forward selection terminates at the step where the SBC reaches a (local) minimum:

```
selection method=forward(select=SBC choose=AIC);
```

However, the selected model is the first one that has the minimum value of Akaike's information criterion. In some cases, this minimum value might occur at a step much earlier than the final step. In other cases, the AIC might start increasing only if more steps are performed—that is, a larger value is used for the significance level for entry. If you want to minimize AIC, then too many steps are performed in the former case and too few in the latter case. To address this issue, you can use the **STOP=** option to specify a stopping criterion. When you specify a stopping criterion, forward selection continues until a local extremum of the stopping criterion in the sequence of models generated is reached. To be deemed a local extremum, a criterion value at a particular step must be better than its value at the next n steps, where n is known as the “stop horizon.” By default, the stop horizon is three steps, but you can change this by specifying the **STOPHORIZON=** option.

For example, if you specify the following statement, then forward selection terminates at the step where the effect to be added at the next step would produce a model that has an AIC statistic larger than the AIC statistic of the current model:

```
selection method=forward(select=SBC stop=AIC) stophorizon=1;
```

In most cases, provided that the stop horizon is long enough that the local extremum of the named criterion occurs before the final step, specifying either of the following statements selects the same model, but more steps are done in the first case:

```
selection method=forward(select=SL choose=CRITERION);
selection method=forward(select=SL stop=CRITERION);
```

In some cases, there might be a better local extremum that cannot be reached if you specify the **STOP=** option but can be found if you use the **CHOOSE=** option. Also, you can use the **CHOOSE=** option in preference to the **STOP=** option if you want to examine how the named criterion behaves as you move beyond the step where the first local minimum of this criterion occurs.

You can specify both the **CHOOSE=** and **STOP=** options. You can also use these options together with options that specify size-based limits on the selected model. You might want to consider models that are generated by forward selection and have at most some fixed number of effects, but select from within this set based on a criterion that you specify. For example, specifying the following statements requests that forward selection continue until there are 20 effects in the final model and chooses among the sequence of models the one that has the smallest value of the corrected Akaike's information criterion:

```
selection method=forward(stop=none maxeffects=20 choose=AICC);
```

You can also combine these options to select a model where one of two conditions is met. For example, the following statement chooses whatever occurs first between a local minimum of the Schwarz Bayesian information criterion (SBC) and a local minimum of the corrected Akaike's information criterion (AICC):

```
selection method=forward(stop=AICC choose=SBC);
```

You can find discussion and references to studies about criteria for variable selection in Burnham and Anderson (2002), along with some cautions and recommendations.

Examples of Forward Selection Specifications

The following statement adds effects that at each step produce the lowest value of the SBC statistic and stops at the step where adding any effect would increase the SBC statistic:

```
selection method=forward stophorizon=1;
```

The following statement adds effects that at each step produce the lowest value of the AIC statistic and stops at the first step whose AIC value is smaller than the AIC value at the next three steps:

```
selection=forward(select=AIC);
```

Backward Elimination

This section applies to the following procedures: CNTSELECT and SEVSELECT.

METHOD=BACKWARD specifies the backward elimination technique. This technique starts from the full model, which includes all independent effects. Then effects are deleted one by one until a stopping condition is satisfied. At each step, the effect that shows the smallest contribution to the model is deleted.

Just as with forward selection, you can use the **SELECT=** option to change the criterion that is used to assess effect contributions. You can also specify a stopping criterion in the **STOP=** option and use a **CHOOSE=** option to provide a criterion for selecting among the sequence of models produced. For more information, see the discussion in the section “Forward Selection” on page 102.

Examples of Backward Selection Specifications

The following statement removes effects that at each step produce the largest value of the Schwarz Bayesian information criterion (SBC) statistic and stops at the step where removing any effect increases the SBC statistic:

```
selection method=backward stophorizon=1;
```

The following statement bases removal of effects on the corrected Akaike's information criterion (AICC) and stops at the first step whose AICC value is smaller than the AICC value at the next three steps:

```
selection method=backward(select=AICC);
```

Stepwise Selection

This section applies to the following procedures: CNTSELECT and SEVSELECT.

METHOD=STEPWISE specifies the stepwise method, which modifies the forward selection technique by allowing effects already in the model to be removed.

Just as you can in forward selection and backward elimination, you can use the **SELECT=** option to change the criterion that is used to assess effect contributions. You can also use the **STOP=** option to specify a stopping criterion and use a **CHOOSE=** option to provide a criterion for selecting among the sequence of models produced. For more information, see the section “[Forward Selection](#)” on page 102.

The procedures in this book support further modification to the stepwise method. In the standard stepwise method, no effect can enter the model if removing any effect currently in the model would yield an improved value of the selection criterion. In the modification, you can use the **COMPETITIVE** option to specify that addition and deletion of effects should be treated competitively. The selection criterion is evaluated for all models that are produced by deleting an effect from the current model or by adding an effect to this model. The action that most improves the selection criterion is the action taken.

Examples of Stepwise Selection Specifications

The following statement requests stepwise selection based on the SBC criterion:

```
selection method=stepwise;
```

First, if removing any effect yields a model that has a lower SBC statistic than the current model, then the effect that produces the smallest SBC statistic is removed. If removing any effect increases the SBC statistic, then provided that adding some effect lowers the SBC statistic, the effect that produces the model that has the lowest SBC is added.

The following statement requests the stepwise method where effects enter and leave based on the AIC statistic, but with the following extra check: if any effect to be added or removed yields a model whose SBC statistic is greater than the SBC statistic of the current model, then the stepwise method terminates at the current model.

```
selection method=stepwise(select=AIC stop=SBC) stophorizon=1;
```

The following statement requests stepwise selection that is based on the AICC criterion and treats additions and deletions competitively:

```
selection method=stepwise(select=AICC competitive);
```

Each step evaluates the AICC statistics that correspond to the removal of any effect in the current model or the addition of any effect to the current model and chooses the addition or removal that produced the minimum value, provided that this minimum is lower than the AICC statistic of the current model.

Forward-Swap Selection

This section applies to the following procedures: CNTSELECT and SEVSELECT.

METHOD=FORWARDSSWAP specifies the forward-swap selection method, which is an extension of the forward selection method. The forward-swap selection method incorporates steps that improve a model by replacing an effect in the model with an effect that is not in the model.

The forward-swap selection method begins by finding the one-effect model that produces the best value of the selection criterion. Then another effect (the one that yields the greatest improvement in the selection criterion) is added. After the two-effect model is obtained, each of the effects in the model is compared to each effect that is not in the model. For each comparison, the forward-swap method determines whether removing one effect and replacing it with the other effect improves the selection criterion. After comparing all possible swaps, the forward-swap method makes the swap that produces the greatest improvement in the selection criterion. Comparisons begin again, and the process continues until the forward-swap method finds that no other swap could improve the selection criterion. Thus, the two-variable model that is produced is considered the “best” two-variable model that the technique can find. Another variable is then added to the model, and the comparing-and-swapping process is repeated to find the “best” three-variable model, and so on.

The difference between the stepwise selection method and the forward-swap selection method is that all swaps are evaluated before any addition is made in the forward-swap method. In the stepwise selection method, the “worst” effect might be removed without considering what adding the “best” remaining effects might accomplish. Because the forward-swap method needs to examine all possible pairwise effect swaps at each step of the selection process, the forward-swap method is much more computationally expensive than the stepwise selection method; it might not be appropriate for models that contain a large number of effects.

Informative Missingness

This section applies to the following procedures: CNTSELECT, CPANEL, CQLIM, CSPATIALREG, and SEVSELECT.

The concept of informative missingness is one way to account for missing values in statistical analyses and, in particular, statistical modeling. Missing values can be a problem because they reduce the amount of available data. When you work with classification variables (factors, which are leveled variables), you can treat a missing value as an actual level of the variable and allow it to participate in the analysis.

However, when continuous variables have missing values, the observation is removed from the analysis. In data that have many missing values, removing observations can reduce the amount of available data greatly, and the sets of observations used in one model versus another model can vary based on which variables are included in the model.

Of course, there are many reasons for missing values, and substituting values for missing values has to be done with caution. For example, the famous Framingham Heart study data set contains 5,209 observations on subjects in a longitudinal study that helped understand the relationship between smoking, cholesterol,

and coronary heart disease. One of the variables in the data set is AgeCHDdiag. This variable represents the age at which a patient was diagnosed with coronary heart disease (CHD). If you include this variable in a statistical model, only 1,449 observations are available, because the value cannot be observed unless a patient has experienced CHD. Including this variable acts as a filter that reduces the analysis set to the subjects who have CHD. You cannot impute the value for subjects where the variable has a missing value, because you cannot impute an age at which someone who has not had CHD would have contracted coronary heart disease.

With informative missingness, you are not so much substituting imputed values for the missing values as you are modeling the missingness. Consider a simple linear regression model:

$$y = \beta_0 + \beta_1 x + \epsilon$$

Suppose that some of the values for the regressor variable x are missing. The fitted model uses only observations for which y and x have been observed.

In order to predict the outcome y for an observation that has a missing x , either you assume that y is missing or you substitute a value (such as the average value, $\bar{x}$) for the missing x . Because the estimate for the intercept is in the simple linear regression model, the predicted value would be the average response of the nonmissing values, $\bar{y}$.

With informative missingness, you extend the model by adding extra effects for each effect that contains at least one continuous variable. In the simple linear regression model, you add one column to the model and slightly change the content of the x variable:

$$y = \beta_0 + \beta_1 x^* + \beta_2 x_{\text{miss}} + \epsilon_1$$

The variable x^* contains the original values of x if they are not missing, and the average of x otherwise:

$$x^* = \begin{cases} x & \text{if } x \text{ is not missing} \\ \bar{x} & \text{otherwise} \end{cases}$$

The variable x_{miss} is a dummy variable whose value is 1 when x is missing, and 0 otherwise:

$$x_{\text{miss}} = \begin{cases} 1 & \text{if } x \text{ is missing} \\ 0 & \text{otherwise} \end{cases}$$

The fitted model is not the same model that results from substituting $\bar{x}$ for the missing values during training, because the model that simply substitutes $\bar{x}$ for the missing values is

$$y = \beta_0 + \beta_1 x^* + \epsilon_2$$

The informative missing model has an extra parameter, and unless all values of x_{miss} are 0 (in which case there are no missing values), the informative missing model has a higher R-square value, because it picks up more variation.

The parameter estimate for β_2 measures the amount by which the predicted value differs from a predicted value at $\bar{x}$.

Multithreading

Threading refers to the organization of computational work into multiple tasks (processing units that can be scheduled by the operating system). A task is associated with a thread. Multithreading refers to the concurrent execution of threads. When multithreading is possible, substantial performance gains can be realized compared to sequential (single-threaded) execution. The number of threads spawned by a procedure in this book is determined by your installation.

The tasks that are multithreaded by procedures in this book are primarily defined by dividing the data that are processed on a single machine among the threads—that is, the procedures implement multithreading through a data-parallel model. For example, if the input data table has 1,000 observations and the procedure is running on four threads, then 250 observations are associated with each thread. All operations that require access to the data are then multithreaded. These operations include the following (not all operations are required for all procedures):

- variable levelization
- effect levelization
- formation of the initial crossproducts matrix
- formation of approximate Hessian matrices for candidate evaluation during model selection
- objective function calculation
- gradient calculation
- Hessian calculation
- scoring of observations

In addition, operations on matrices such as sweeps can be multithreaded provided that the matrices are of sufficient size to realize performance benefits from managing multiple threads for the particular matrix operation.

Choosing an Optimization Algorithm

This section applies to the SEVSELECT procedure.

First- or Second-Order Algorithms

The factors that go into choosing a particular optimization technique for a particular problem are complex. Trial and error can be involved.

For many optimization problems, computing the gradient takes more computer time than computing the function value. Computing the Hessian sometimes takes *much* more computer time and memory than computing the gradient, especially when there are many decision variables. Unfortunately, optimization techniques that do not use some kind of Hessian approximation usually require many more iterations than techniques that do use a Hessian matrix, and as a result the total run time of these techniques is often longer. Techniques that do not use the Hessian also tend to be less reliable. For example, they can terminate more easily at stationary points than at global optima.

Table 4.19 shows which derivatives are required for each optimization technique.

Table 4.19 Derivatives Required

Algorithm	First-Order	Second-Order
TRUREG	x	x
NEWRAP	x	x
NRRIDG	x	x
QUANEW	x	-
DBLDOG	x	-
CONGRA	x	-
NMSIMP	-	-

The second-derivative methods TRUREG, NEWRAP, and NRRIDG are best for small problems for which the Hessian matrix is not expensive to compute. Sometimes the NRRIDG algorithm can be faster than the TRUREG algorithm, but TRUREG can be more stable. The NRRIDG algorithm requires only one matrix with $p(p+1)/2$ double words; TRUREG and NEWRAP require two such matrices. Here, p denotes the number of parameters in the optimization.

The first-derivative methods QUANEW and DBLDOG are best for medium-sized problems for which the objective function and the gradient can be evaluated much faster than the Hessian. In general, the QUANEW and DBLDOG algorithms require more iterations than TRUREG, NRRIDG, and NEWRAP, but each iteration can be much faster. The QUANEW and DBLDOG algorithms require only the gradient to update an approximate Hessian, and they require slightly less memory than TRUREG or NEWRAP.

The first-derivative method CONGRA is best for large problems for which the objective function and the gradient can be computed much faster than the Hessian and for which too much memory is required to store the (approximate) Hessian. In general, the CONGRA algorithm requires more iterations than QUANEW or DBLDOG, but each iteration can be much faster. Because CONGRA requires only a factor of p double-word memory, many large applications can be solved only by CONGRA.

The no-derivative method NMSIMP is best for small problems for which derivatives are not continuous or are very difficult to compute.

Each optimization method uses one or more convergence criteria that determine when it has converged. An algorithm is considered to have converged when any one of the convergence criteria is satisfied. For example, under the default settings, the QUANEW algorithm converges if $\text{ABSGCONV} < 1\text{E-}5$, $\text{FCONV} < 2 \times \epsilon$, or $\text{GCONV} < 1\text{E-}8$.

By default, procedures in this book apply the NRRIDG algorithm because it can take advantage of multi-threading in Hessian computations and inversions. If the number of parameters becomes large, specifying the QUANEW technique, which is a first-order method with good overall properties, is recommended.

Algorithm Descriptions

The following subsections provide details about each optimization technique and follow the same order as Table 4.19.

Trust Region Optimization (TRUREG)

The trust region method uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function $f(\boldsymbol{\beta})$ have continuous first- and second-order derivatives inside the feasible region.

The trust region method iteratively optimizes a quadratic approximation to the nonlinear objective function within a hyperelliptic trust region with radius Δ that constrains the step size that corresponds to the quality of the quadratic approximation. The trust region method is implemented based on Dennis, Gay, and Welsch (1981), Gay (1983), and Moré and Sorensen (1983).

The trust region method performs well for small- to medium-sized problems, and it does not need many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the dual quasi-Newton or conjugate gradient algorithms might be more efficient.

Newton-Raphson Optimization with Line Search (NEWRAP)

The NEWRAP technique uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region. If second-order derivatives are computed efficiently and precisely, the NEWRAP method can perform well for medium-sized to large problems, and it does not need many function, gradient, and Hessian calls.

This algorithm uses a pure Newton step when the Hessian is positive-definite and when the Newton step reduces the value of the objective function successfully. Otherwise, a combination of ridging and line search is performed to compute successful steps. If the Hessian is not positive-definite, a multiple of the identity matrix is added to the Hessian matrix to make it positive-definite (Eskow and Schnabel 1991).

In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The line-search method uses quadratic interpolation and cubic extrapolation.

Newton-Raphson Ridge Optimization (NRRIDG)

The NRRIDG technique uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$ and the Hessian matrix $\mathbf{H}(\boldsymbol{\beta}^{(k)})$; thus, it requires that the objective function have continuous first- and second-order derivatives inside the feasible region.

This algorithm uses a pure Newton step when the Hessian is positive-definite and when the Newton step reduces the value of the objective function successfully. If at least one of these two conditions is not satisfied, a multiple of the identity matrix is added to the Hessian matrix.

Because the NRRIDG technique uses an orthogonal decomposition of the approximate Hessian, each iteration of NRRIDG can be slower than that of the NEWRAP technique, which works with a Cholesky decomposition. However, NRRIDG usually requires fewer iterations than NEWRAP.

The NRRIDG method performs well for small- to medium-sized problems, and it does not require many function, gradient, and Hessian calls. However, if the computation of the Hessian matrix is computationally expensive, one of the dual quasi-Newton or conjugate gradient algorithms might be more efficient.

Quasi-Newton Optimization (QUANEW or DUQUANEW)

The dual quasi-Newton method uses the gradient $\mathbf{g}(\boldsymbol{\beta}^{(k)})$, and it does not need to compute second-order derivatives because they are approximated. It works well for medium-sized to moderately large optimization problems, where the objective function and the gradient can be computed much faster than the Hessian. However, in general the QUANEW technique requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which compute second-order derivatives. The QUANEW technique provides an appropriate balance between the speed and stability required for most nonlinear mixed model applications.

The QUANEW technique implemented by procedures in this book is the dual quasi-Newton algorithm, which updates the Cholesky factor of an approximate Hessian.

In each iteration, a line search is performed along the search direction to find an approximate optimum. The line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α that satisfies

the Goldstein conditions (Fletcher 1987). One of the Goldstein conditions can be violated if the feasible region defines an upper limit of the step size. Violating the left-side Goldstein condition can affect the positive-definiteness of the quasi-Newton update. In that case, either the update is skipped or the iterations are restarted with an identity matrix, resulting in the steepest descent or ascent search direction.

Double-Dogleg Optimization (DBLDOG)

The double-dogleg optimization method combines the ideas of the quasi-Newton and trust region methods. In each iteration, the double-dogleg algorithm computes the step $s^{(k)}$ as the linear combination of the steepest descent or ascent search direction $s_1^{(k)}$ and a quasi-Newton search direction $s_2^{(k)}$:

$$s^{(k)} = \alpha_1 s_1^{(k)} + \alpha_2 s_2^{(k)}$$

The step is requested to remain within a prespecified trust region radius (Fletcher 1987, p. 107). Thus, the DBLDOG subroutine uses the dual quasi-Newton update but does not perform a line search.

The double-dogleg optimization technique works well for medium-sized to moderately large optimization problems, where the objective function and the gradient can be computed much faster than the Hessian. The implementation is based on Dennis and Mei (1979) and Gay (1983), but it is extended for dealing with boundary and linear constraints. The DBLDOG technique generally requires more iterations than the TRUREG, NEWRAP, and NRRIDG techniques, which require second-order derivatives; however, each of the DBLDOG iterations is computationally cheap. Furthermore, the DBLDOG technique requires only gradient calls for the update of the Cholesky factor of an approximate Hessian.

Conjugate Gradient Optimization (CONGRA)

Second-order derivatives are not required by the CONGRA algorithm and are not even approximated. The CONGRA algorithm can be expensive in function and gradient calls, but it requires only $O(p)$ memory for unconstrained optimization. In general, many iterations are required to obtain a precise solution, but each of the CONGRA iterations is computationally cheap.

The CONGRA subroutine should be used for optimization problems with large p . For the unconstrained or boundary-constrained case, CONGRA requires only $O(p)$ bytes of working memory, whereas all other optimization methods require order $O(p^2)$ bytes of working memory. During p successive iterations, uninterrupted by restarts or changes in the working set, the conjugate gradient algorithm computes a cycle of p conjugate search directions. In each iteration, a line search is performed along the search direction to find an approximate optimum of the objective function. The line-search method uses quadratic interpolation and cubic extrapolation to obtain a step size α that satisfies the Goldstein conditions. One of the Goldstein conditions can be violated if the feasible region defines an upper limit for the step size.

Nelder-Mead Simplex Optimization (NMSIMP)

The Nelder-Mead simplex method does not use any derivatives and does not assume that the objective function has continuous derivatives. The objective function itself needs to be continuous. This technique is quite expensive in the number of function calls, and it might be unable to generate precise results for $p \gg 40$.

The original Nelder-Mead simplex algorithm is implemented and extended to boundary constraints. This algorithm does not compute the objective for infeasible points, but it changes the shape of the simplex adapting to the nonlinearities of the objective function. This change contributes to an increased speed of convergence and uses a special termination criterion.

Overview: CARIMA Procedure

The CARIMA procedure analyzes and forecasts equally spaced univariate time series data, by using the autoregressive integrated moving-average (ARIMA) or autoregressive moving-average (ARMA) model.

An ARIMA model predicts a value in a response time series as a linear combination of its own past values and past errors (also called shocks or innovations).

The ARIMA approach was first popularized by Box and Jenkins (1976), and ARIMA models are often referred to as Box-Jenkins models.

The CARIMA procedure provides a comprehensive set of tools for parameter estimation and for forecasting univariate time series. It also offers a high degree of flexibility in the types of ARIMA models that you can analyze; it supports seasonal, subset, and factored ARIMA models. For each fitted model, PROC CARIMA prints parameter estimates along with standard errors and *p*-values, and it prints multistep-ahead variable forecasts along with confidence intervals.

Before you use PROC CARIMA, you should exercise care and judgment and be familiar with Box-Jenkins methods.

The ARIMA class of time series models is complex and powerful, and some degree of expertise is needed to use them correctly.

PROC CARIMA requires SAS Cloud Analytic Services (CAS) in order to run, and it does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CARIMA Procedure

This section outlines the use of the CARIMA procedure and gives a cursory description of the ARIMA modeling process for readers who are less familiar with these methods.

Given an input data table that contains numerous time series variables recorded at a specific frequency, the CARIMA procedure can fit an ARIMA model to the series and produce forecasts.

For example, suppose that the input data table `mylib.Sales` contains sales data that were recorded monthly, the variable that represents time is `Date`, and the forecasts are to be recorded in the output data table `mylib.NextYear`. If you believe that sales in the current month are affected only by sales in the previous month, then you can use the CARIMA procedure to fit an AR(1) model and forecasts sales for the next four months as follows:

```
data mylib.sales;
  format date date9.;
  input date : date9. shoes socks laces dresses
          coats shirts ties belts hats blouses;
  datalines;
01JAN1994 3557 3718 6368.80 575 987 10.8200 15.0000 102.600 12410 15013

proc carima data=mylib.sales outfor=mylib.nextyear;
  id date interval=month;
  identify _numeric_;
  estimate p =1;
  forecast lead=4;
```

```
run;
```

These statements assume that the SAS library is named mylib, but you can substitute any appropriately named SAS library. These statements generate forecasts for every numeric variable in the input data table mylib.Sales for the next four months and store these forecasts in the output data table mylib.NextYear. Other output data tables can be specified to store the parameter estimates and summary data.

The CARIMA procedure can forecast time series data, whose observations are equally spaced by a specific time interval (for example, monthly or weekly), or transactional data, whose observations are not spaced with respect to any particular time interval.

Given an input data table that contains transactional variables that are not recorded at any specific frequency, the CARIMA procedure accumulates the data to a specific time interval and forecasts the accumulated series. For an example, see “[Example 5.1: Seasonal Model for the Airline Series](#)” on page 131.

Syntax: CARIMA Procedure

The following statements are available in the CARIMA procedure:

```
PROC CARIMA options ;
BY variables ;
ID variable INTERVAL= interval < options > ;
IDENTIFY variable-list ;
ESTIMATE < options > ;
FORECAST < options > ;
```

The PROC CARIMA and IDENTIFY statements are required. The CARIMA procedure supports multiple IDENTIFY, ESTIMATE, and FORECAST statements. The FORECAST statement forecasts all variables in the *variable-list* that is specified in the preceding IDENTIFY statement according to the model that is specified in the preceding ESTIMATE statement. If no ESTIMATE statement is specified before a FORECAST statement, then prediction is carried out according to a white noise model.

Functional Summary

The statements and options that control the CARIMA procedure are summarized in [Table 5.1](#).

Table 5.1 Functional Summary

Description	Statement	Option
Statements		
Specify data tables and options	PROC CARIMA	
Request BY-group processing	BY	
Specify the variables to model	IDENTIFY	
Specify the variables to estimate	ESTIMATE	
Specify the variables to forecast	FORECAST	

Table 5.1 *continued*

Specify the method for trimming the data in the BY groups	ID	TRIMID =

The following sections describe the PROC CARIMA statement and then describe the other statements in alphabetical order.

PROC CARIMA Statement

PROC CARIMA *options* ;

You can specify the following *options*:

DATA=*libref.data-table*

names the input data table for PROC CARIMA to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 114.

data-table specifies the name of the input data table.

OUT=*libref.data-table*

names the output data table to contain the forecasts of the variables specified in the subsequent FORECAST statements. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the **DATA=** option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 114.

If an ID statement is specified, its variable is also included in the OUT= data table and its values are accumulated on the basis of the ACCUMULATE= option in the ID statement.

OUTEST=*libref.data-table*

names the output data table to contain the model parameter estimates and the associated test statistics and probability values. The OUTEST= data table is useful for evaluating the significance of the model parameters and understanding the model dynamics.

OUTFOR=*libref.data-table*

names the output data table to contain the forecast time series components (actual, predicted, lower confidence limit, upper confidence limit, prediction error, and prediction standard error). The OUTFOR= data table is useful for displaying the forecasts in tabular or graphical form.

OUTSUM=*libref.data-table*

names the output data table to contain the summary statistics and the forecast summation. The summary statistics are based on the accumulated time series when the ACCUMULATE= or SETMISSING= option is specified in the ID statement. The OUTSUM= data table is useful for summarizing results when large numbers of series are forecast.

BY Statement

BY *variables* ;

A BY statement can be used with PROC CARIMA to obtain separate dummy variable definitions for groups of observations that are defined by the BY *variables*.

ESTIMATE Statement

ESTIMATE < *options* > ;

The ESTIMATE statement specifies the type of ARIMA model to be fit for the *variable* in the preceding IDENTIFY statement.

You can specify the following *options*:

CONVERGE=*value*

specifies the convergence criterion, where *value* is a number between 0 and 1, exclusive. Convergence is assumed when the largest change in the estimate for any parameter is less than the specified *value*. If the absolute value of the parameter estimate is greater than 0.01, the relative change is used; otherwise, the absolute change in the estimate is used. By default, CONVERGE=0.001.

DELTA=*value*

specifies the perturbation value for computing numerical derivatives, where *value* is a number between 0 and 1, exclusive. By default, DELTA=0.001.

DIFF=(*value-list*)

specifies the degrees of differencing for the *variable-list* that is specified in the preceding IDENTIFY statement. For example, you can specify DIFF=(1) to take a first-order difference for all variables specified in the *variable-list* of the preceding IDENTIFY statement. If you have monthly data and expect seasonal patterns, you can specify DIFF=(1,12) to difference all variables in the *variable-list* of the preceding IDENTIFY statement twice: once at lag 1, and then again at lag 12. Each analyzed series is then the difference between the current period-to-period change in the specified variable and the change 12 periods ago. Each value in the *value-list* is an integer greater than 0. By default, DIFF=(0).

MAXITER=*value*

specifies the maximum number of iterations, where *value* is a positive integer. By default, MAXITER=50.

METHOD=*method-name*

specifies the estimation method to be used.

You can specify the following forecasting *method-names*:

- CLS** specifies the conditional least squares method.
- ML** specifies the maximum likelihood method.
- ULS** specifies the unconditional least squares method.

By default, METHOD=CLS.

MU=value

specifies a constant term for the ARIMA model, where *value* is a number. By default, MU=0.

NOINT=0 | 1

specifies whether to include an intercept in the model. You can specify the following values:

- 0** includes an intercept term in the model.
- 1** omits the intercept term from the model. This suppresses the fitting of a constant (or intercept) parameter in the model. That is, the value specified in the MU value is omitted.

By default, NOINT=0.

NOSTABLE=0 | 1

specifies whether to restrict the candidate estimates for the autoregressive and moving average parameters in the stationary and invertible regions, respectively. You can specify the following values:

- 0** restrict candidate estimates in stable and invertible regions.
- 1** do not restrict candidate estimates.

By default, NOSTABLE=0.

P=value

specifies the degree of the autoregressive polynomial, where *value* is an integer greater or equal than 0. By default, P=0.

Q=value

specifies the degree of the moving average polynomial, where *value* is an integer greater or equal than 0. By default, Q=0.

SINGULAR=value

specifies the criterion for checking singularity, where *value* is a number between 0 and 1, exclusive. If a pivot of a sweep operation is less than *value*, the matrix is deemed singular. Sweep operations are performed on the Jacobian matrix during final estimation and on the covariance matrix when preliminary estimates are obtained. The default is 1E-7.

TRANSFORM=transform-option

specifies the time series transformation to apply to the series in the ESTIMATE statement. You can specify the following *transform-options*:

- BOXCOX(*n*)** applies a Box-Cox transformation with parameter number, *n*, where *n* is a number between -5 and 5.
- LOG** applies a logarithmic transformation.
- LOGISTIC** applies a logistic transformation.
- NONE** does not apply a transformation.
- SQRT** applies a square-root transformation.

By default, TRANSFORM=NONE.

FORECAST Statement

FORECAST < options > ;

The FORECAST statement forecasts the future values of the variable list that is specified in the preceding IDENTIFY statement according to the model that is fitted in the preceding ESTIMATE STATEMENT.

You can specify any number of FORECAST statements. You can specify the following *options*:

ALPHA=*number*

specifies the significance level to use in computing the confidence limits of the forecast, where *number* must be between 0 and 1. By default, ALPHA=0.05, which produces 95% confidence intervals.

LEAD=*number*

specifies the *number* of periods ahead to forecast, where *number* must be an integer greater than or equal to 0. By default, LEAD=0.

ID Statement

ID *variable* **INTERVAL**=*interval* < options > ;

The ID statement names a numeric *variable* that identifies observations in the input and output data tables. The ID variable's values are assumed to be SAS date or datetime values. In addition, the ID statement specifies the (desired) frequency that is associated with the time series. The ID statement *options* also specify how to accumulate the observations and how to align the time ID values to form the time series to be forecast. The specified information affects all variables that are specified in subsequent IDENTIFY statements. If an ID statement is not specified, the observation number (with respect to the BY group) is used as the time ID.

You must specify the **INTERVAL**=*interval* option:

INTERVAL=*interval*

specifies the frequency of the input time series or the frequency for the time series to be accumulated from the input data. For example, if the input data consist of quarterly observations, then specify INTERVAL=QTR. For example, INTERVAL=QTR implies a seasonal cycle of length 4. If the ACCUMULATE= option is also specified, the INTERVAL= option determines the time periods for the accumulation of observations.

The basic intervals are YEAR, SEMIYEAR, QTR, MONTH, SEMIMONTH, TENDAY, WEEK, WEEKDAY, DAY, HOUR, MINUTE, SECOND. For more information about the intervals that can be specified, see the “Date Intervals, Formats, and Functions” chapter in *SAS/ETS User's Guide*.

You can also specify the following *options*:

ACCUMULATE=*accumulate-option*

specifies how to accumulate the observations within each time period. The frequency (width of each time interval) is specified in the INTERVAL= option. The ID variable contains the time ID values. Each time ID variable value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent model fitting and forecasting.

This option is particularly useful when there are gaps in the input data or when there are multiple input observations that coincide with a particular time period (for example, transactional data). The EXPAND

procedure in *SAS/ETS User's Guide* offers additional frequency conversions and transformations that can also be useful in creating a time series.

The following *accumulate-options* determine how the observations are accumulated within each time period on the basis of the ID variable and the frequency that is specified in the INTERVAL= option:

TOTAL SUM	accumulates observations based on the total sum of their values.
AVERAGE AVG	accumulates observations based on the average of their values.
MINIMUM MIN	accumulates observations based on the minimum of their values.
MAXIMUM MAX	accumulates observations based on the maximum of their values.
N	accumulates observations based on the number of nonmissing observations.
NMISS	accumulates observations based on the number of missing observations.
STDDEV STD	accumulates observations based on the standard deviation of their values.
CSS	accumulates observations based on the corrected sum of squares of their values.
USS	accumulates observations based on the uncorrected sum of squares of their values.

By default, ACCUMULATE=TOTAL.

If the ACCUMULATE= option is specified, the SETMISSING= option is useful for specifying how to treat accumulated missing values. If missing values should be interpreted as 0, then specify SETMISSING=0. For more information about accumulation, see the section “[Accumulation](#)” on page 125.

ALIGN=*align-option*

controls the alignment of SAS date or datetime values that are used to identify the time period of output observations. Although any date or datetime value within the time period can identify the time period, the ALIGN= option requests that the representative date or datetime for the time period be calculated as the beginning date or datetime of the time period, the ending date or datetime of the time period, or the middle date or datetime of the time period. In addition to aligning the time ID values consistently for observations you supply, the ALIGN= option specifies the method for calculating the time ID values for observations in the forecast and backcast time periods, which often you do not supply. You can specify the following *align-options*:

BEGINNING BEG B	represents each time period by using the beginning SAS date or datetime value of the time period.
ENDING END E	represents each time period by using the ending SAS date or datetime value of the time period.
MIDDLE MID M	represents each time period by using the middle SAS date or datetime value of the time period. The middle is calculated as the average of the beginning and ending values.

By default, ALIGN=BEGINNING.

END=*date | datetime*

specifies a SAS date or datetime literal value that represents the end of the data. If the last time ID *variable* value is less than the END= value, the series is extended with missing values. If the last time ID *variable* value is greater than the END= value, the series is truncated. For example, **END= '1jan2008'**D requests that data for time periods after the first of January 2008 not be used. The option **END= "&sysdate"**D uses the automatic macro variable SYSDATE to extend or truncate the series to the current date. This option and the START= option can be used to ensure that data associated with each BY group contain the same number of observations.

FORMAT=*format*

specifies the SAS format for the time ID values. If you omit this option, the default format is implied by the INTERVAL= option.

SETMISSING=*option*

specifies how to interpret missing values (either actual or accumulated) in the accumulated time series. You can specify the following values to determine how to interpret missing values:

<i>n</i>	interprets a missing value as having the value <i>n</i> . You can specify any number for <i>n</i> , but not a missing value. If a missing value indicates a 0 value, specify SETMISSING=0. You typically use SETMISSING=0 for transactional data because the absence of recorded data usually implies no activity.
MISSING	interprets a missing value as a missing value. Use this option if a missing value indicates an unknown value.
AVERAGE AVG	interprets a missing value as the average value of all accumulated nonmissing values in the span of the series.
MINIMUM MIN	interprets a missing value as the minimum value of all accumulated nonmissing values in the span of the series.
MEDIAN MED	interprets a missing value as the median value of all accumulated nonmissing values in the span of the series.
MAXIMUM MAX	interprets a missing value as the maximum value of all accumulated nonmissing values in the span of the series.
FIRST	interprets a missing value as the first nonmissing value of all accumulated nonmissing values in the span of the series.
LAST	interprets a missing value as the last nonmissing value of all accumulated nonmissing values in the span of the series.
PREVIOUS PREV	interprets a missing value as the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	interprets a missing value as the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

By default, SETMISSING=MISSING.

START=*date* | *datetime*

specifies a SAS date or datetime literal value that represents the beginning of the data. If the first time ID variable value is greater than the START= value, the series is prefixed with missing values. If the first time ID variable value is less than the START= value, the series is truncated. This option and the END= option can be used to ensure that data associated with each BY group contain the same number of observations.

TRIMID=*method*

specifies the method for trimming the data in the BY groups. The output time ID variable span that is calculated by the *method* is dependent on the input time ID variable span, irrespective of missing values of the time series variables. Depending on the *method* and the input time ID variable data, leading or trailing missing values can be added to the time series variables.

After the output time ID variable span is calculated by the *method*, the ending value of the output time ID variable is recalculated according to the value of the LEAD= option (if one is specified).

You can specify one of the following *methods*:

- NONE** uses the same starting and ending values of the output time ID variable for all BY groups. The span of the output time ID variable includes all values that are input as a time ID value for all BY groups. The time series variables are extended with leading or trailing missing values as required.
- LEFT** uses the identifying date for the first time period that is input for the BY group as the starting value of the output time ID variable for each BY group. The time series values in each BY group are not extended with leading missing values. The ending value of the time ID variable is the same for all BY groups. The time series variables are extended with trailing missing values as required.
- RIGHT** uses the identifying date for the last time period that is input for the BY group as the ending value of the output time ID variable for each BY group. The time series values in each BY group are not extended with trailing missing values. The starting value of the time ID variable is the same for all BY groups. The time series variables are extended with leading missing values as required.
- BOTH** uses the span of the input time ID variable for the BY group as the span of the output time ID variable for each BY group. The time series values in each BY group are not extended with leading or trailing missing values.

By default, TRIMID=NONE.

IDENTIFY Statement

IDENTIFY *variable-list* ;

The identify statement specifies the variables you want to model. Specify one or more variables in a space-separated *variable-list*.

Details: CARIMA Procedure

The CARIMA procedure can be used to fit ARIMA models either to time series data or to as transactional data. If the data are transactional, then the procedure must first accumulate the data into a time series before it can forecast them. The procedure uses the sequential steps in [Table 5.2](#) to produce forecasts, with the options that control the step listed to the right.

Table 5.2 PROC CARIMA Processing Steps and Control Options

Step	Operation	Options	Statement
1	Accumulation	ACCUMULATE=	ID
2	Missing value interpretation	SETMISSING=	ID
3	Parameter estimation	P=, Q=	ESTIMATE
4	Inverse transformation	TRANSFORM, DIFF	ESTIMATE
5	Forecasting	LEAD=	FORECAST

Each of the steps shown in [Table 5.2](#) is described in the following sections.

Accumulation

If the ACCUMULATE= option is specified in the ID statement, data table observations are accumulated within each time period. The frequency (width of each time interval) is specified in the INTERVAL= option, and the ID variable contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data table contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series that is used in subsequent analyses by the CARIMA procedure.

For example, suppose a data table contains the following observations:

```
19MAR1999    10
19MAR1999    30
11MAY1999    50
12MAY1999    20
23MAY1999    20
```

If the INTERVAL=MONTH option is specified in the ID statement, all the preceding observations fall within three time periods: March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows:

- If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).
- If the ACCUMULATE=TOTAL option is specified, the resulting time series is

```
O1MAR1999    40
O1APR1999    .
O1MAY1999    90
```

- If the ACCUMULATE=AVERAGE option is specified, the resulting time series is

```
O1MAR1999    20
O1APR1999    .
O1MAY1999    30
```

- If the ACCUMULATE=MINIMUM option is specified, the resulting time series is

```
O1MAR1999    10
O1APR1999    .
O1MAY1999    20
```

- If the ACCUMULATE=MEDIAN option is specified, the resulting time series is

```
O1MAR1999    20
O1APR1999    .
O1MAY1999    20
```

- If the ACCUMULATE=MAXIMUM option is specified, the resulting time series is

```
O1MAR1999    30
O1APR1999    .
O1MAY1999    50
```

- If the ACCUMULATE=FIRST option is specified, the resulting time series is

```
O1MAR1999    10
O1APR1999    .
O1MAY1999    50
```

- If the ACCUMULATE=LAST option is specified, the resulting time series is

```
O1MAR1999    30
O1APR1999    .
O1MAY1999    20
```

- If the ACCUMULATE=STDDEV option is specified, the resulting time series is

O1MAR1999	14.14
O1APR1999	.
O1MAY1999	17.32

As you can see from the preceding examples, even though the data table observations contained no missing values, the accumulated time series can have missing values.

Missing Value Interpretation

After the data have been accumulated to form a time series on the basis of the `INTERVAL=` and the `ACCUMULATE=` options, missing values are interpreted. Sometimes missing values should be interpreted as unknown values. In this case, you can specify the `SETMISSING=` option to interpret how to treat missing values. In other situations, missing values are known, such as when missing values are created from accumulation and the absence of an observation should be interpreted the observation having the value 0. In this case, you can specify `SETMISSING=0` in order to treat missing observations as 0 values. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and interpreted time series is used in subsequent analyses.

Parameter Estimation

The default method for estimating parameters is conditional least squares. You can also use maximum likelihood estimation and unconditional least squares, by specifying the corresponding value in the `METHOD=` option in the `ESTIMATE` statement.

Transformations

If the `TRANSFORM=` option is specified in the `ESTIMATE` statement, the time series is transformed before the parameters are estimated and the series is forecast. Only strictly positive series can be transformed. An error is generated when the `TRANSFORM=` option is used with a nonpositive series.

Forecasting

After the model parameters are estimated, one-step-ahead forecasts are generated for the full range of the accumulated and optionally transformed time series data, and multistep forecasts are generated from the end of the time series to the future time period as specified in the `LEAD=` option. If there are missing values at the end of the time series, the forecast horizon will be greater than that specified by the `LEAD=` option.

Data Table Output

The CARIMA procedure can create the OUT=, OUTEST=, OUTFOR=, and OUTSUM= data tables. These data tables contain the variables that are listed in the BY, ID, and IDENTIFY statements, in addition to statistics that are related to the parameters estimated by the ESTIMATE statement. In general, if a forecasting step that is related to an output data table fails, the values of that step are not recorded or are set to missing in the related output data table and appropriate error or warning messages (or both) are recorded in the log.

OUT= Data Table

The OUT= data table contains the variables that are specified in the BY, ID, and IDENTIFY statements. If the ID statement is specified, its variable values are aligned and extended according to the values of ALIGN= and INTERVAL= options. The values of the variables that are specified in the IDENTIFY statements are accumulated according to the values of the ACCUMULATE= option, and missing values are interpreted according to the values of the SETMISSING= option.

If any forecasting steps fail for a particular variable, the variable is extended by missing values.

OUTEST= Data Table

The OUTEST= data table contains the variables that are specified in the BY and IDENTIFY statements and the variables in the following list.

NAME	Variable name
MODEL	Forecasting model
MODELVAR	Model variable
DSVAR	Data table variable
VARTYPE	Variable type
TRANSFORM	Transformation
COMPONENT	Component
COMPMODEL	Component model
PARM	Parameter name
FACTOR	Factor
LAG	Lag
SHIFT	Shift
EST	Value of parameter estimate
STDERR	Standard error of parameter estimate
TVALUE	<i>t</i> values of parameter estimate
STDERR	<i>p</i> -values of parameter estimate

If the parameter estimation step fails for a particular variable, no observations are output to the OUTEST= data table for that variable.

OUTFOR= Data Table

The OUTFOR= data table contains the variables that are specified in the BY and IDENTIFY statements and the variables in the following list.

NAME	Variable name
ID Variable	Values of the variable specified in the ID statement
ACTUAL	Actual values
PREDICT	Predicted values
ERROR	Prediction errors
STD	Prediction standard errors
UPPER	Upper confidence limits
LOWER	Lower confidence limits

If the forecasting step fails for a particular variable, no observations are recorded in the OUTFOR= data table for that variable. If the TRANSFORM= option is specified, the values in the preceding IDENTIFY statement are the inverse transform forecasts. If the MEDIAN option is specified, the median forecasts are stored; otherwise, the mean forecasts are stored.

OUTSUM= Data Table

The OUTSUM= data table contains the variables that are specified in the BY statement and the variables in the following list. The OUTSUM= data table records the summary statistics for each variable that is specified in an IDENTIFY statement.

The following variables that are related to summary statistics are based on the ACCUMULATE= and SETMISSING= options:

NAME	Variable name
NOBS	Number of observations
N	Number of nonmissing observations
NMISS	Number of missing observations
MIN	Minimum value
MAX	Maximum value
MEAN	Mean value
STDDEV	Standard deviation
STATUS	forecasting status (nonzero values imply that no forecast was generated for the series)
START	Starting date of each series
END	Ending date of each series
STARTOBS	Beginning observation number of each series
ENDOBS	Ending observation number of each series

Printed Output

The CARIMA procedure always prints a summary of the processing that is performed on the time series data. This is extremely useful for gauging the work that is performed by the CAS server when it executes PROC CARIMA.

The CARIMA procedure also prints by default the parameter estimates of fitted models in the ParameterEstimates table and the multistep-ahead variable forecasts in the Forecasts table. The name of the modeled variable is printed in the VariableInfo table.

You can also print parameter estimates, variable forecasts, and other summary statistics by using targeted data queries to subset and display the information from the tables that PROC CARIMA produces. For example, you might want to print results in the OUTFOR= data table only for BY groups that have a particular _STATUS_ value in the OUTSUM= table.

ODS Table Names

The CARIMA procedure assigns a name to each table that it creates. You can use this name to refer to the table when using the Output Delivery System (ODS) to select tables and create output data tables. These names are listed in [Table 5.3](#).

Table 5.3 ODS Tables Produced in the CARIMA Procedure

ODS Table Name	Description	Option
Forecasts	Forecast components, such as prediction, prediction standard error, lower and upper confidence limits	Default
OutInfo	Summary of the processing that is performed on the time series data	Default
ParameterEstimates	Parameter estimates	Default
VariableInfo	Name of the variable specified in the IDENTIFY statement	Default

Example: CARIMA Procedure

Example 5.1: Seasonal Model for the Airline Series

The airline passenger data have been used in time series analysis literature as an example of a nonstationary seasonal time series.

The following statements plot the air data:

```
proc sgplot data=sashelp.air;  
  series x = date y = air;  
run;
```

Output 5.1.1 indicates that the series is nonstationary and seasonal.

Output 5.1.1 Airline Passenger Data

The following DATA step loads the air data into a CAS session. The DATA step assumes that the SAS library is named mylib, but you can substitute any appropriately named SAS library.

```
data mylib.myair;
  set sashelp.air;
run;
```

You can use the following statements to fit an $ARIMA(0,1,1) \times (0,1,1)_{12}$ model without a mean term to the logarithms of the airline passengers series. The model estimates and forecasts are stored in the data tables `mylib.cariest` and `mylib.carifor`.

```
proc carima data=mylib.myair outest=mylib.cariest outfor=mylib.carifor;
  id date interval=month;
  identify air;
  estimate q=(1)(12) noint method = ML transform = log diff = (1,12);
  forecast lead = 4;
run;
```

Output 5.1.2 shows the summary of the time series processing.

Output 5.1.2 Summary of Time Series Processing
The CARIMA Procedure

Processing Summary	
CAS table	MYAIR
Number of analysis variables	1
Number of rows read	288
Number of groups read	1
Memory for group packages (KB)	15
Time to load groups (seconds)	0.0108208656
Minimum time ID	JAN1949
Maximum time ID	DEC1960
Minimum time periods	144
Maximum time periods	144
Number of nodes run	4
Number of nodes with data	3
Number of nodes with groups	1
Number of threads budgeted	1
Minimum thread group count	0
Maximum thread group count	1
Minimum threads active	1
Maximum threads active	1
Number of groups processed by submitted code	1
Number of groups failing	0
Elapsed time to process groups (seconds)	0.0632238388

Output 5.1.3 shows the name of the modeled variable.

Output 5.1.3 Variable Information

Variable Info	
Variable Name	AIR

Output 5.1.4 shows the parameter estimates from the fitted model.

Output 5.1.4 Parameter Estimates

Maximum Likelihood Estimates					
Parameter	Estimate	Standard Error	t Value	Pr > t	Lag
MA1_1	0.401936	0.079877	5.03	<.0001	1
MA2_12	0.556862	0.084027	6.63	<.0001	12

Output 5.1.5 shows the multistep-ahead variable forecasts.

Output 5.1.5 Variable Forecasts

Forecasts for AIR using Model 1				
95%				
Time ID	Forecast	Std Error	Confidence Limits	
JAN1961	450.7320	16.6829	418.9155	484.3014
FEB1961	426.1129	18.3793	391.2224	463.2533
MAR1961	479.5664	23.2533	435.6018	526.7297
APR1961	493.1052	26.2879	443.5853	546.5997

The following statements plot the forecasts that are produced by the $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model. The plot is shown in Output 5.1.6.

```
proc sgplot data=mylib.carifor;
  series x=date y=actual / markers lineattrs=(color=red)
                                markerattrs=(symbol=circlefilled color=red);
  series x=date y=predict / markers lineattrs=(color=blue)
                                markerattrs=(symbol=asterisk color=blue);
  refline '01JAN1959'd / axis=x;
run;
```

Overview: CAUSALDISCOVERY Procedure

The directed acyclic graph (DAG) is critical for causal inference, which has been widely applied in many fields, including machine learning, artificial intelligence (AI), economics, finance, medicine, and so on. However, usually the structure of a DAG must be provided by experts, because learning the structure of a DAG is a well-known NP-hard problem. The CAUSALDISCOVERY procedure supports two algorithms for DAG structure learning: the topological order permutation (TOP) algorithm and the minimizing conditional variance (MCV) algorithm. Both algorithms are fast and accurate; they can reach 100% accuracy in many cases, even when there are hundreds of variables.

In addition to DAG structure learning, PROC CAUSALDISCOVERY can simulate a DAG (ground truth) and generate samples that are based on the simulated DAG. It can also evaluate the accuracy of the learned DAG by computing several metrics for comparing the estimated DAG to the ground truth.

Because PROC CAUSALDISCOVERY runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;  
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the `CASHOST` and `CASPORT` of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the `TERMINATE` option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “Introduction to Shared Concepts” on page 54 in Chapter 4, “Shared Concepts.”

Getting Started: CAUSALDISCOVERY Procedure

This example illustrates how the CAUSALDISCOVERY procedure estimates the DAG from which the data are generated, in order to solve a seven-variable DAG structure learning problem.

The following DATA step produces the simulated data set to be used in the example:

```
data one;
  input x1 - x7;
datalines;
  0.6712068564    -0.2826079580    -0.5349256450    -0.8261341320
 -3.0394109400    -1.8825135390     5.2510795861
 -0.7107886740    -2.4798707050     1.2698001196    -6.2078732110
 -14.3827270100   -11.0299665000    20.9643672460

... more lines ...

 -0.5282917840    0.4435880321     -0.6905104940    0.4259155417
 -0.1943036260    0.6881816788     -0.6409083280
 -0.3955187900    -0.5117192740    -1.0742776010    0.7085965238
 2.1642802138     1.5589762381     -2.7343111790
;
```

What is the relationship among these seven variables? That is the question that the DAG structure learning is trying to answer. Note that as the number of variables increases, the number of DAGs increases superexponentially. When the number of variables is seven, there are more than one billion seven-variable DAGs. Finding the one true DAG from which the data are generated is not easy. However, PROC CAUSALDISCOVERY might help you find that DAG in seconds or even less than a second.

The following DATA step loads the data set one into the data table one in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.one; set one; run;
```

The following code inputs the data set, specifies the variables, and names the output data table. The INITMETHOD=DATA option in the LEARN statement shows whether there is any difference between the topological order of the final estimated DAG and the order that is specified in the VAR statement.

```
proc causaldiscovery;
  var x1 - x7;
  learn data=mylib.one / initmethod=data out=mylib.oest;
run;
```

The number of observations is shown in [Figure 6.1](#).

Figure 6.1 Number of Observations
The CAUSALDISCOVERY Procedure

Number of Observations Read	10000
Number of Observations Used	10000

The algorithm information is shown in Figure 6.2.

Figure 6.2 Algorithm Information
The CAUSALDISCOVERY Procedure

Algorithm Information	
Algorithm	Topological Order Permutation
Initialization Method	Data
Maximum Iterations	200
Parallel	Yes
Seed	1

The topological orders are shown in Figure 6.3. This table shows that there is a difference between the topological order of the final estimated DAG and the order that is specified in the VAR statement.

Figure 6.3 Initial and Final Topological Orders

Topological Orders		
Variable	Initial Order	Final Order
x1	1	1
x2	2	3
x3	3	2
x4	4	4
x5	5	6
x6	6	5
x7	7	7

The estimated full DAG that is expressed as the adjacency matrix is shown in Figure 6.4. In an adjacency matrix $W = (w_{ij})$, element w_{ij} is either 0 or 1. If $w_{ij} = 0$, this means that there is no edge from variable i to variable j ; otherwise, there is an edge from variable i to variable j (that is, variable i is a parent of variable j , or variable j is a child of variable i).

Figure 6.4 Estimated Full Adjacency Matrix

Estimated Full Adjacency Matrix							
Variable	x1	x2	x3	x4	x5	x6	x7
x1	0	1	1	1	1	1	1
x2	0	0	0	1	1	1	1
x3	0	1	0	1	1	1	1
x4	0	0	0	0	1	1	1
x5	0	0	0	0	0	0	1
x6	0	0	0	0	1	0	1
x7	0	0	0	0	0	0	0

The estimated DAG based on the significance level 0.0001% is shown in [Figure 6.5](#).

Figure 6.5 Estimated Adjacency Matrices Based on the Significance Level 0.0001%

Estimated Adjacency Matrices								
Alpha	Variable	x1	x2	x3	x4	x5	x6	x7
1E-6	x1	0	1	0	0	0	0	0
	x2	0	0	0	1	1	0	0
	x3	0	1	0	1	0	1	0
	x4	0	0	0	0	0	1	0
	x5	0	0	0	0	0	0	0
	x6	0	0	0	0	1	0	1
	x7	0	0	0	0	0	0	0

As shown in the adjacency matrix in [Figure 6.5](#), X1 and X3 have no parents; X2's parents are X1 and X3; X4's parents are X2 and X3; X5's parents are X2 and X6; X6's parents are X3 and X4; and X7's parent is X6. [Figure 6.6](#) shows this seven-variable DAG.

Figure 6.6 Estimated DAG

In fact, this estimated DAG is the true DAG for the data generating process, as shown in the following SAS code:

```

data one;
  call streaminit('pcg', 12345);
  x1 = 0; x2 = 0; x3 = 0; x4 = 0;
  x5 = 0; x6 = 0; x7 = 0;
  do i = 1 to 10000;
    x1 = rand('Normal');
    x3 = rand('Normal');
    x2 = x1 - 0.5*x3 + rand('Normal');
    x4 = 1.5*x2 - x3 + rand('Normal');
    x6 = 0.5*x3 + 2*x4 + rand('Normal');
    x5 = -x2 + 1.5*x6 + rand('Normal');
    x7 = -2*x6 + rand('Normal');
    output;
  end;
  drop i;
run;

```

Syntax: CAUSALDISCOVERY Procedure

The following statements are available in the CAUSALDISCOVERY procedure. Items within angle brackets (<>) are optional.

```

PROC CAUSALDISCOVERY ;
  DISPLAY <table-list> </options> ;
  DISPLAYOUT table-spec-list </options> ;
  EVALUATE <ESTDAG=libref.data-table> <TRUEDAG=libref.data-table> </options> ;
  LEARN <DATA=libref.data-table> <OUTDAG=libref.data-table> </options> ;
  ROOTVAR variable-list ;
  SIMULATE <OUT=libref.data-table> <OUTDATA=libref.data-table> </options> ;
  VAR variable-list ;

```

The PROC CAUSALDISCOVERY and VAR statements are required. Table 6.1 lists the required options in each statement and in combinations of statements. Note that the procedure does nothing if you do not specify a SIMULATE, LEARN, or EVALUATE statement. By default, the procedure uses output tables from one statement as input for another statement when you specify any of these three statements together. If you specify an input table in the Omitted Options column, it is ignored unless it existed on the libref before the procedure call.

Table 6.1 Required Options in the CAUSALDISCOVERY Procedure

Statement(s)	Required Options	Omitted Options
EVALUATE	ESTDAG=	
LEARN	TRUEDAG=	
LEARN and EVALUATE	DATA=	
	DATA= in LEARN	ESTDAG= in EVALUATE
	OUTDAG= in LEARN	

Table 6.1 *continued*

Statement(s)	Required Options	Omitted Options
SIMULATE	TRUEDAG= in EVALUATE	
SIMULATE and EVALUATE	None	
SIMULATE and LEARN	ESTDAG= in EVALUATE	TRUEDAG= in EVALUATE
SIMULATE , LEARN , and EVALUATE	OUT= in SIMULATE	
	OUTDATA= in SIMULATE	DATA= in LEARN
	OUT= in SIMULATE	DATA= in LEARN
	OUTDATA= in SIMULATE	ESTDAG= in EVALUATE
	OUTDAG= in LEARN	TRUEDAG= in EVALUATE

Functional Summary

The statements and options available in the CAUSALDISCOVERY procedure are summarized in Table 6.2. The sections after the table describe each statement in alphabetical order, following the PROC CAUSALDISCOVERY statement.

Table 6.2 Functional Summary

Description	Statement	Option
Input Data Table Options		
Specifies the input table containing the estimated DAG structure	EVALUATE	ESTDAG=
Specifies the input data table containing the true adjacency matrix	EVALUATE	TRUEDAG=
Specifies the input data table	LEARN	DATA=
Output Data Table Options		
Writes the accuracy metrics to an output data set	EVALUATE	OUT=
Writes the initial and final topological orders, as well as the matrices of parameter estimates, standard deviations, <i>t</i> values, and <i>p</i> -values to an output data set	LEARN	OUT=
Writes the learned DAG to an output data set	LEARN	OUTDAG=
Writes the iteration history to an output data set	LEARN	OUTITER=
Writes the parents and children of variables and paths of the estimated DAGs to an output data set	LEARN	OUTPATH=
Writes the simulated DAG to an output data set	SIMULATE	OUT=
Writes the simulated data to an output data set	SIMULATE	OUTDATA=
Writes the topological order of the simulated DAG to an output data set	SIMULATE	OUTORDER=
Writes the parameter values to an output data set	SIMULATE	OUTPARAM=
Variables		
Specifies the variables to be generated based on the DAG	VAR	

Table 6.2 *continued*

Description	Statement	Option
Root Variables		
Specifies the assumed root variables of the DAG	ROOTVAR	
Learning Algorithm Options		
Specifies the DAG structure learning algorithm	LEARN	ALGORITHM=
Specifies that the DAG structure learning algorithm perform calculations by using graphics processing unit (GPU) hardware	LEARN	GPU
Specifies the method to use for determining the initial topological order	LEARN	INITMETHOD=
Specifies the maximum number of iterations	LEARN	MAXITER=
Specifies the random number seed value for the random number generator	LEARN	SEED=
Specifies that all structure learnings are to be performed in a single thread	LEARN	NONPARALLEL
Simulation Options		
Specifies the number of edges	SIMULATE	NEDGES=
Specifies the sample size	SIMULATE	NOBS=
Specifies how the noise terms are generated	SIMULATE	NOISE()
Specifies how the parameter values are generated	SIMULATE	PARM()
Specifies the seed value for the random number generator	SIMULATE	SEED=
Options to Control the Estimated DAGs		
Specifies the significance levels on whose basis the DAG edges are determined	LEARN	ALPHA=
Output Control Options		
Specifies the ODS tables to display	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	

PROC CAUSALDISCOVERY Statement

PROC CAUSALDISCOVERY ;

The PROC CAUSALDISCOVERY statement invokes the CAUSALDISCOVERY procedure.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[ODS Table Names](#)” on page 158. A path is a table name that is prefixed with dot-separated grouping information. For example, a TopoOrders table that the procedure produces has the path *Causaldiscovery.TopoOrders*. A partial pathname does not include all groups; for example, *TopoOrders* is a partial pathname for *Causaldiscovery.TopoOrders*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, *TopoOrders* selects *Causaldiscovery.TopoOrders*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/order/” selects all pathnames that contain the substring “order”; in particular, the *Causaldiscovery.TopoOrders* table is selected. Specifying “!/order/” selects all pathnames that do not contain the substring “order”; in particular, the *Causaldiscovery.TopoOrders* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 158. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

EVALUATE Statement

EVALUATE < **ESTDAG**=*libref.data-table* > < **TRUEDAG**=*libref.data-table* > < / *options* > ;

The EVALUATE statement specifies the options that are related to the accuracy evaluation of the DAG structure learning. You can specify the following options:

ESTDAG=*libref.data-table*

ESTADJ=*libref.data-table*

specifies the input data table that contains the adjacency matrix for the estimated DAGs. If you specify both the EVALUATE and LEARN statements, you should specify the OUTDAG= option table in the LEARN statement but not specify the ESTDAG= option table in the EVALUATE statement. This is because the OUTDAG= output table is used as the ESTDAG= input table in the EVALUATE statement. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 136.

TRUEDAG=*libref.data-table*

TRUEADJ=*libref.data-table*

specifies the input data table that contains the adjacency matrix for the true DAG. If you specify both the EVALUATE and SIMULATE statements, you should specify the OUT= option table in the SIMULATE statement but not specify the TRUEDAG= option table in the EVALUATE statement. This is because the OUT= output table is used as the TRUEDAG= input table in the EVALUATE statement. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

You can also specify the following *option* after a slash (/):

OUT=*libref.data-table*

writes the accuracy metrics to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

LEARN Statement

LEARN < **DATA=***libref.data-table* > < **OUTDAG=***libref.data-table* > < / *options* > ;

The LEARN statement specifies the options that are related to the DAG structure learning. You can specify the following options:

DATA=*libref.data-table*

specifies the input data table. If you specify both the LEARN and SIMULATE statements, you should specify the OUTDATA= option table in the SIMULATE statement but not specify the DATA= option table in the LEARN statement. This is because the OUTDATA= output table is used as the DATA= input table in the LEARN statement.

OUTDAG=*libref.data-table*

writes the estimated DAGs to the specified output data table. You must specify this option if you also specify the EVALUATE statement; this table is then used as the ESTDAG= input table in the EVALUATE statement. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136. .

You can also specify the following *options* after a slash (/):

ALGORITHM=MCV | TOP

ALG=MCV | TOP

specifies the DAG structure learning algorithm. You can specify the following values:

MCV specifies the minimizing conditional variance (MCV) algorithm.

TOP specifies the topological order permutation (TOP) algorithm.

By default, ALGORITHM=TOP.

ALPHA=number | (number-list)

specifies the significance level on whose basis the edges in the DAG are determined. If you specify a *number-list*, several DAGs are included in the OUTDAG= option table, one for each value in the *number-list*. The *number* and all numbers in the *number-list* must be between 0 and 1. By default, ALPHA=0.000001.

GPU

specifies that the DAG structure learning algorithm perform calculations by using graphics processing unit (GPU) hardware. When ALGORITHM=MCV, this option is ignored.

INITMETHOD=DATA | RANDOM | VARIANCE

specifies the method to use for determining the initial topological order. You can specify the following values:

DATA	matches the order of the variables in the VAR statement.
RANDOM	determines the order randomly.
VARIANCE	determines the order by using the ascending order of variance of variables in the VAR statement.

By default, INITMETHOD=VARIANCE.

MAXITER=number

specifies the maximum number of iterations. The *number* must be a nonnegative integer. By default, MAXITER=200.

NONPARALLEL

specifies that all structure learnings are to be performed in a single thread on a single machine. If you omit this option, the structure learning algorithm uses as many threads or CPUs as possible.

OUT=libref.data-table

writes the initial and final topological orders, as well as the matrices of parameter estimates, standard errors, *t* values, and *p*-values to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

OUTITERHIST=libref.data-table**OUTITER=libref.data-table**

writes the iteration history to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

OUTPATH=libref.data-table**OUTP=libref.data-table**

writes the parents and children of variables and paths of the estimated DAGs to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

SEED=number

specifies the random number seed value for the random number generator. If the seed value is 0, a random number stream is generated by using the time of day from the computer's clock. Seed values greater than 0 generate reproducible random number sequences. By default, SEED=1.

ROOTVAR Statement

ROOTVAR *variable-list* ;

The ROOTVAR statement specifies the root variable names in the input data table that you specify in the DATA= option in the LEARN statement. Root variables are variables that have no parents or incoming edges. They serve only as potential parents of other variables during the causal discovery process.

SIMULATE Statement

SIMULATE < **OUT=***libref.data-table* > < **OUTDATA=***libref.data-table* > < / *options* > ;

The SIMULATE statement specifies the options to be used to first simulate a DAG and then generate the observations from the simulated DAG. You can specify the following options:

OUT=*libref.data-table*

OUTDAG=*libref.data-table*

writes the simulated DAG to the specified output data table. You must specify this option if you also specify the EVALUATE statement; this table is then used as the TRUEDAG= input table in the EVALUATE statement. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

OUTDATA=*libref.data-table*

writes the simulated data to the specified output data table. You must specify this option if you also specify the LEARN statement; this table is then used as the DATA= input table in the LEARN statement. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

You can also specify the following *options* after a slash (/):

NEDGES=*number*

E=*number*

specifies the number of edges in the DAG. The *number* must be a nonnegative integer. By default, $NEDGES = \min(d(d-1)/2, 2d)$, where d is the number of nodes or variables.

NOBS=*number*

N=*number*

SAMPLESIZE=*number*

specifies the number of observations in the OUTDATA= option table. The *number* must be a positive integer. By default, NOBS=10000.

NOISE(DIST=distribution)

specifies how the noise terms in the structural causal model are generated. You can specify the following *distribution*:

GAUSSIAN(gaussian-options)**NORMAL(gaussian-options)**

specifies the Gaussian distribution for the noise. You can specify the following *gaussian-options*:

MEAN=number

specifies the mean for the distribution. By default, MEAN=0.

STD=number

specifies the standard deviation for the distribution. By default, STD=1.

VAR=number

specifies the variance for the distribution. By default, VAR=1.

NOTE: You can specify the STD= option or the VAR= option, but not both.

OUTORDER=libref.data-table

writes the topological order of the simulated DAG to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

OUTPARAM=libref.data-table

writes the parameter values to the specified output data table. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 136.

PARM(DIST=distribution)

specifies how to generate the parameter values that represent the weights of the edges. You can specify the following *distribution*:

UNIFORM(uniform-options)

specifies the uniform distribution for the parameter values. You can specify the following *uniform-options*:

LB=number

specifies the lower bound of the distribution. By default, LB=-1.

EXCLLB=number

specifies the lower bound of the excluded range. By default, EXCLLB=-0.5.

EXCLUB=number

specifies the upper bound of the excluded range. By default, EXCLUB=0.5.

UB=number

specifies the upper bound of the distribution. By default, UB=1.

The range of the uniform distribution is (LB, EXCLLB] U [EXCLUB, UB). The middle (EXCLLB, EXCLUB) range is excluded to avoid numerical instability in the simulated data set, as is common practice in the DAG literature.

SEED=number

specifies the random number seed value for the random number generator. If the seed value is 0, a random number stream is generated by using the time of day from the computer's clock. Seed values greater than 0 generate reproducible random number sequences. By default, SEED=1.

VAR Statement

VAR *variable-list* ;

The VAR statement specifies the variable names in the input data table that you specify in the DATA= option in the LEARN statement. If you omit the DATA= option in the LEARN statement, or if you omit the LEARN statement, the VAR statement creates the list of variable names for the SIMULATE and EVALUATE statements.

Details: CAUSALDISCOVERY Procedure

DAG Structure Learning Overview

A graph consists of nodes (also known as vertices) and edges. A directed acyclic graph (DAG) is a type of graph such that (1) the edge has direction from one node to another, and (2) if you start from one node and travel along the directed edges, you cannot come back to the starting node; that is, there is no directed loop. [Figure 6.7](#) shows an example of a DAG. By contrast, the graph in [Figure 6.8](#) is not a DAG because the edge between X1 and X3 has no direction. The graph in [Figure 6.9](#) is not a DAG because there is a directed loop from X1 to X3, then to X2, and then back to X1. The graph in [Figure 6.10](#) is not a DAG because there is a directed edge from X5 to X5 itself, which makes a directed loop.

Figure 6.7 Example of a DAG

Figure 6.8 First Example of a Graph That Is Not a DAG

Figure 6.9 Second Example of a Graph That Is Not a DAG

Figure 6.10 Third Example of a Graph That Is Not a DAG

If there is a directed edge from node i to node j , then node i is the parent of node j , or equivalently, node j is the child of node i . All parents of a node construct the parent set of that node. Another important concept is the topological order of a DAG, which defines the order of the nodes so that one node's parent set must be a subset of the nodes whose orders are lower than the order of that node. For example, the DAG shown in Figure 6.7 has the topological order $\{X2, X1, X3, X5, X4\}$, and $X2$ is a root variable that has no parents.

DAGs play a critical role in causal inference (Pearl 1988), which has been widely used in many fields, including machine learning (Bayesian networks), AI, economics, finance, medicine, and so on. The goal of DAG structure learning is to estimate the DAG from which the data are generated for a given data set; that is, in the DAG structure learning problem, the DAG's nodes correspond to the variables in the data set one to one, which is a known correspondence, but whether there is an edge between any two nodes (in this case, variables) and what is the direction of that edge (if it exists) should be estimated. It is well known that the DAG structure learning problem is NP-hard (Chickering, Heckerman, and Meek 2004). The searching space of DAGs is superexponential with respect to the number of variables. The exact recursive equation (Murphy 2007) to calculate the number of DAGs for a given number of variables is

$$G(d) = \sum_{k=1}^d (-1)^{(k+1)} 2^{k(d-k)} C(d, k) G(d-k)$$

where d is the number of variables and $C(d, k)$ is the number of combinations of choosing k items from d different items, where $C(d, k) = \frac{d!}{k!(d-k)!}$. The following SAS code calculates the number of DAGs for up to 20 variables. The results are shown in Output 6.11.

```

* g(n) = sum_{k=1}^n { (-1)^(k+1) * C(n, k) * 2^{k(n-k)} * g(n-k) };
%let M = 20;
proc iml;
  g = J(&M.+1, 1, 1);
  f = J(&M.+1, 1, 1);
  do n = 1 to &M.;
    f[n+1] = f[n]*n;
    g[n+1] = 0;
    do k = 1 to n;
      g[n+1] = g[n+1] +
        (-1)##(k+1) * (f[n+1]/f[k+1]/f[n-k+1]) * 2##(k*(n-k)) * g[n-k+1];
    end;
  end;
end;

```

```

dat = (1:&M.)` || g[2:&M.+1];
cols={'d' 'nDags'};
create dagcount from dat[colname=cols];
append from dat;
close;
quit;
proc print data=dagcount noobs label;
  label d="Number of Variables" nDags="Number of DAGs";
run;

```

It is not surprising that although there are exact algorithms for DAG structure learning, those algorithms cannot be practical when you have a large number of variables. In general, there are two approaches to learning the DAG structure: one is score-based, and the other is constraint-based. The score-based approach uses a score function to measure how well a structure fits the training data and tries to find the structure that has the best score. The constraint-based approach uses independence tests to determine the edges and the directions. For more information, see Peters, Janzing, and Schölkopf (2017), Glymour, Zhang, and Spirtes (2019), Kitson et al. (2021), and the references therein.

PROC CAUSALDISCOVERY supports two types of score-based algorithms: the topological order permutation (TOP) algorithm (see Chen, Huang, and Chvosta 2022) and the minimizing conditional variance (MCV) algorithm (see Chen et al. 2024).

Topological Order Permutation (TOP) Algorithm

The topological order permutation (TOP) algorithm searches for the correct topological order first, instead of directly searching the whole DAG structure. This algorithm assumes that the full DAG with the correct topological order would lead to the best score. The full DAG (also known as a transitive tournament) is the DAG in which there is a directed edge between any two variables; that is, if there are d variables, then in the full DAG there are $d(d - 1)/2$ directed edges. Note that the topological order and the full DAG map one-to-one to each other. That is, for a given topological order, there is one and only one full DAG that corresponds to it; for a given full DAG, there is one and only one topological order that corresponds to it. Hence, sometimes the terms full DAG and topological order are used interchangeably.

For the data generating process, the DAG is linked with the structural causal model (SCM), which is described by the following equation:

$$X_i = f_i(\text{pa}(X_i), U_i), i = 1, \dots, d$$

where d is the number of variables, X_i is the i th variable, $\text{pa}(X_i)$ is the parent set of variable X_i , U_i is the error term for i th equation, $U = (U_i)$ follows some joint distribution $G(\cdot)$, and $f_i(\cdot)$ is some function for the i th equation.

In PROC CAUSALDISCOVERY, the TOP algorithm assumes that the data generating process follows the linear SCM with additive errors:

$$X_i = \sum_{X_j \in \text{pa}(X_i)} \tilde{w}_{ji} * X_j + U_i, i = 1, \dots, d$$

where the weighted adjacency matrix $\tilde{W} = (\tilde{w}_{ji})$ and $\tilde{w}_{ji}$ is nonzero if and only if X_j is the parent of X_i , and U_i is independent of any other errors. When you specify the ROOTVAR statement, those specified root variables are not approximated but serve only as parents of other variables. They appear only on the right-hand side of the equation. This additional information is used to improve the algorithm's efficiency and accuracy.

The score in the TOP algorithm for the preceding linear SCM is defined as the sum of square errors (SSRs); that is, for a given data set,

$$L = \sum_{n=1}^N \sum_{i=1}^d (X_i - \sum_{X_j \in \text{pa}(X_i)} \tilde{w}_{ji} * X_j)^2$$

where L stands for the loss and is also the score, and N is the sample size. The goal is to find the full DAG that minimizes the loss. This process can be done iteratively. Each iteration has two steps:

1. For the current topological order, evaluate the score.
2. Enumerate the neighbors of the current topological order and evaluate their scores. If none of them have a better score than the current topological order, then stop and return the current topological order as the solution. Otherwise, set the current topological order as the topological order that corresponds to the best score among the neighbors, and start the next iteration.

For a topological order $r = (r_i)_{i=1,\dots,d}$, its neighbors in the TOP algorithm are defined as the set of topological orders $\{r' : r' \in A \cup B \cup C\}$. An element $r^{(A)}$ in set A is the topological order such that there exist k_1 and k_2 , $1 \leq k_1 < k_2 \leq d$, for any i , $1 \leq i \leq d$, where the i th element of $r^{(A)}$ satisfies the following conditions:

- If $r_i < k_1$ or $r_i > k_2$, then $r_i^{(A)} = r_i$.
- If $r_i = k_2$, then $r_i^{(A)} = k_1$.
- If $k_1 \leq r_i < k_2$, then $r_i^{(A)} = r_i + 1$.

An element $r^{(B)}$ in set B is the topological order such that there exist k_1 and k_2 , $1 \leq k_1 < k_2 \leq d$, for any i , $1 \leq i \leq d$, where the i th element of $r^{(B)}$ satisfies the following conditions:

- If $r_i < k_1$ or $r_i > k_2$, then $r_i^{(B)} = r_i$.
- If $r_i = k_1$, then $r_i^{(B)} = k_2$.
- If $k_1 < r_i \leq k_2$, then $r_i^{(B)} = r_i - 1$.

An element $r^{(C)}$ in set C is the topological order such that there exist k_1 and k_2 , $1 \leq k_1 < k_2 \leq d$, for any i , $1 \leq i \leq d$, where the i th element of $r^{(C)}$ satisfies the following conditions:

- If $r_i \neq k_1$ and $r_i \neq k_2$, then $r_i^{(C)} = r_i$.
- If $r_i = k_1$, then $r_i^{(C)} = k_2$.
- If $r_i = k_2$, then $r_i^{(C)} = k_1$.

There are $d(d-1)/2$ elements in each of the sets A , B , and C , because there are $d(d-1)/2$ unique pairs of (k_1, k_2) such that $1 \leq k_1 < k_2 \leq d$. However, some element might appear in both sets or all three sets. The neighbors in the algorithm define the searching space in an iteration, which is critical for the TOP algorithm to work well and also distinguishes the TOP algorithm from all other structure learning algorithms.

After the best topological order (and equivalently, the full DAG) is found, the post-processing step is performed to delete the unnecessary edges in the full DAG. This can be regarded as a variable selection problem: for each variable X_i , $i = 1, \dots, d$, assuming that $\text{pa}_{\text{full}}(X_i)$ denotes the parent set of X_i by the full DAG, select $\text{pa}(X_i) \subseteq \text{pa}_{\text{full}}(X_i)$ according to some criterion. For example, compare the p -value of the estimated w_{ji} to a given significance level; that is, X_j is the parent of X_i if and only if the p -value is smaller than the given significance level.

As shown in “[Example 6.1: Simulation Study of DAG Structure Learning](#)” on page 159, the TOP algorithm is fast and accurate even when the number of variables reaches 100.

Minimizing Conditional Variance (MCV) Algorithm

The minimizing conditional variance (MCV) algorithm assumes that the data generating process follows the linear structural causal model with additive errors. Like the TOP algorithm, it uses the sum of square errors as the score function. It further assumes that the topological order $r = (r_1, \dots, r_d)$ corresponds to the best score if $\forall i \in [1, \dots, d], \forall j > i, \text{Var}(X_{r_i} | X_{r_1}, \dots, X_{r_{i-1}}) \leq \text{Var}(X_{r_j} | X_{r_1}, \dots, X_{r_{i-1}})$.

The MCV algorithm consists of two steps:

1. Determine a topological order of the DAG.
2. Find a correct set of edges between the nodes according to the topological order.

The algorithm determines the topological order as follows:

1. Initialize the topological order r .
2. Iteratively use the minimum conditional variance assumption to update the parent list, and use the updated parent list to compute conditional variances.

After the topological order is determined, the postprocessing step is performed as in the TOP algorithm.

The MCV algorithm is as accurate as the TOP algorithm and is much faster, especially when the number of variables is large. As shown in “[Example 6.2: Learning a Large DAG by Using the MCV Algorithm](#)” on page 163, the MCV algorithm can accurately estimate a DAG that has 1,000 nodes in just a few seconds on one CPU.

Causal Discovery with Panel Data

Broadly, PROC CAUSALDISCOVERY works by stepping through all the possible DAGs for a given set of variables, calculating the sum of the squares of the residuals through OLS regression to find the minimum, and removing the insignificant edges to output the final DAG.

When the input data are a panel data set, the procedure supports one-way or two-way fixed effects that it estimates through dummy-variable OLS regression. Fixed-effects dummies represent unobserved unit-level or time-level heterogeneity and are assumed to be exogenous by construction; they have no causal parents within the model. Such variables are therefore designated as root variables and are excluded from the final DAG output.

Missing Values

All observations are read, but only observations without missing values are used in the DAG estimation.

Data Table Output

PROC CAUSALDISCOVERY can create the output data tables listed in Table 6.2. The information in each table is described in the following sections.

OUT= Data Table Generated by the EVALUATE Statement

The output data table contains the following variables:

alpha	values of the significance levels on whose basis the edges in the estimated DAG are determined
nee	number of extra edges
nme	number of missing edges
nre	number of reversed edges
shd	structural Hamming distance, defined as the total number of edges that need to be added, deleted, or reversed to transform the estimated DAG into the true DAG
tpv	true positive rate, defined as the ratio between the number of edges that are correctly identified in the estimated DAG and the total number of edges in the true DAG. It is set to a missing value if the true DAG has no edges.

OUT= Data Table Generated by the LEARN Statement

The DAG estimation details table contains the following variables:

outType	output type. The values are R_I, R_F, EST, STD, TVL, and PVL, where R_I and R_F are, respectively, the initial and final topological order, and EST, STD, TVL, and PVL are, respectively, the estimation value, standard error, t value, and p -value of weights.
rowId	index of the variables
VarName_ i	column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement

OUTDAG= Data Table Generated by the LEARN Statement

The estimated DAG table contains the following variables:

rowId	index of the variables
alpha	values of the significance levels on whose basis the edges in the estimated DAG are determined
VarName_ i	column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement

OUTITER= Data Table Generated by the LEARN Statement

The iteration history table contains the following variables:

iterId	index of the iteration
loss	loss value

OUTPATH= Data Table Generated by the LEARN Statement

The paths of estimated DAGs table contains the following variables:

outType	output type. The values are ADJ and DAG, where ADJ indicates that no significance level has been applied to the weight matrix, and DAG indicates that the significance level α , whose value is listed in the α column, has been used.
rowId	index of the variables
α	values of the significance levels on whose basis the edges in the estimated DAG are determined
variable	name of the variables
parents	parents list
children	children list
pathlhsp	parent at LHS path. For example, if X_1 is the parent of X_3 and X_5 , then the path is $X_1 \Rightarrow X_3 X_5$
pathlhsc	child at LHS path. For example, if X_1 is the child of X_2 and X_4 , then the path is $X_1 \Leftarrow X_2 X_4$

OUT= Data Table Generated by the SIMULATE Statement

The simulated DAG output table contains the following variables:

rowId	index of the variables
VarName_ i	column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement

OUTDATA= Data Table Generated by the SIMULATE Statement

The simulated data output table contains the following variables:

VarName_ i	column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement
--------------	---

OUTORDER= Data Table Generated by the SIMULATE Statement

The topological order output table contains the following variables:

VarName_ i column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement

OUTPARAM= Data Table Generated by the SIMULATE Statement

The parameter values output table contains the following variables:

rowId index of the variables

VarName_ i column for the i th variable, $i = 1, \dots, d$, where d is the number of variables in the VAR statement

ODS Table Names

The CAUSALDISCOVERY procedure assigns a name to each table that it creates. You can use this name to refer to the table when using the Output Delivery System (ODS) to select tables and create output data tables. These names are listed in [Table 6.3](#).

Table 6.3 ODS Tables Produced by the CAUSALDISCOVERY Procedure

ODS Table Name	Description	Option
AlgoInfo	Algorithm information	Default
EstAdjMatrices	Estimated adjacency matrices based on significance levels	Default
EstFullAdjMat	Estimated full adjacency matrix	Default
NObs	Observation information	Default
TopoOrders	Initial and final topological orders	Default

Examples: CAUSALDISCOVERY Procedure

Example 6.1: Simulation Study of DAG Structure Learning

This example shows how to use the CAUSALDISCOVERY procedure to study the performance of the TOP algorithm and focuses on DAGs that contain 100 variables. The number of 100-variable DAGs is huge, and far beyond the maximum number that a double-precision number can express. For a data set that contains 100 variables, finding the DAG that is used in the data generating process (DGP) is an almost impossible challenge.

This example checks the accuracy of the TOP algorithm in three cases of different number of edges:

- Sparse: 100-variable, 600-edge DAGs
- Medium: 100-variable, 2,400-edge DAGs
- Full: 100-variable, 4,950-edge DAGs

For each case, 30 trials are examined. In each trial, first the SIMULATE statement simulates a DAG and then generates a 10,000-observation data set based on the simulated DAG; then the LEARN statement estimates the DAG according to the simulated data set; and finally, the EVALUATE statement evaluates the accuracy by comparing the estimated DAG from the LEARN statement to the true simulated DAG from the SIMULATE statement. In the data set simulation, a parameter value that is associated with an edge is uniformly drawn from $(-0.75, -0.4) \cup (0.4, 0.75)$. This specific range is chosen to avoid the numerical issues for the simulated data set, because when the number of edges increases, especially in the full DAG case, the chance of getting a numerically unstable data set also increases. Here, the numerically unstable data set means that the data set that is expressed as a matrix $X = (x_{i,n})_{n=1,\dots,10000}^{i=1,\dots,100}$ is not numerically full rank, although in theory it should be full rank. In the accuracy evaluation, the counts of three possible mistakes in DAG estimation—namely, missing edges, extra edges, and reverse edges—are reported; the sum of these three counts, the so-called structural Hamming distance (SHD), is also reported; and the final reported criterion is the true positive rate (TPR) for checking how many truly existing directed edges are found.

The SAS macro for a trial is as follows:

```
%macro dagTrial(simId,nNodes,nEdges,nObs,tblEval);
  * simulate DAG and data;
  proc causaldiscovery;
    var coll - col&nNodes.;
    simulate outdata=mylib.sdata out=mylib.sdag / nEdges=&nEdges. nObs=&nObs.
      parm(dist=uniform(lb=-0.75 ub=0.75 excllb=-0.4 exclub=0.4))
      seed=%eval(12345678+&simId.);
  run;

  * learn the DAG structure;
  proc causaldiscovery;
    var coll - col&nNodes.;
    learn data=mylib.sdata outdag=mylib.outdag / maxiter=%eval(5*&nNodes)
      alpha=(0.1 0.01 0.0001 0.000001 0.00000001);
  run;
```

```

        out=mylib.oest ;
run;

* evaluate the accuracy of structure learning;
proc causaldiscovery;
    var coll - col&nNodes.;
    evaluate estdag=mylib.outdag truedag=mylib.sdag / out=mylib.oeval;
run;

data mylib.oeval;
    set mylib.oeval; simID=&simId.;
run;

%if &simId.=1 %then %do;
    %let dataread=mylib.oeval;
%end;
%else %do;
    %let dataread= mylib.&tblEval. mylib.oeval;
%end;

data mylib.&tblEval.;
    set &dataread;
run;
%mend;

```

Alternatively, you can specify all three statements (SIMULATE, LEARN, and EVALUATE) in a single procedure call as follows:

```

%macro dagTrial(simId,nNodes,nEdges,nObs,tblEval);

proc causaldiscovery;
    var coll - col&nNodes.;
    * simulate DAG and data;
    simulate out=mylib.sdag outdata=mylib.sdata /
        nEdges=&nEdges. nObs=&nObs. seed=%eval(12345678+&simId.)
        parm(dist=uniform(lb=-0.75 ub=0.75 excllb=-0.4 exclub=0.4));

    * learn the DAG structure;
    learn outdag=mylib.outdag / maxiter=%eval(5*&nNodes)
        alpha=(0.1 0.01 0.0001 0.000001 0.00000001)
        out=mylib.oest ;

    * evaluate the accuracy of structure learning;
    evaluate / out=mylib.oeval;
run;

data mylib.oeval;
    set mylib.oeval; simID=&simId.;
run;

%if &simId.=1 %then %do;
    %let dataread=mylib.oeval;
%end;
%else %do;

```

```

    %let dataread= mylib.&tblEval. mylib.oeval;
%end;

data mylib.&tblEval.;
    set &dataread;
run;
%mend;

```

The following SAS macros loop over all trials and print the final accuracy report:

```

%macro dagPrint(tblEval);
    data &tblEval.; set mylib.&tblEval.; run;
    proc sort data=&tblEval.; by alpha simId; run;
    proc univariate data=&tblEval. NOPRINT;
        var shd nme nee nre tpr; by alpha;
        output out=ostat
            mean=shdMean nmeMean neeMean nreMean tprMean
            std=shdStd nmeStd neeStd nreStd tprStd;
    run;
    data pstat;
        set ostat;
        pType = 'Mean'; shd = shdMean; nme = nmeMean;
        nee = neeMean; nre = nreMean; tpr = tprMean;
        output;
        pType = 'Std.'; shd = shdStd; nme = nmeStd;
        nee = neeStd; nre = nreStd; tpr = tprStd;
        output;
        keep alpha pType shd nme nee nre tpr;
    run;
    proc print data=pstat noobs label;
        format alpha f10.8;
        format shd nme nee nre tpr f7.2;
        label alpha='Significance Level'
            pType='Type' shd='Structural Hamming Distance'
            nme='N Missing Edges' nee='N Extra Edges'
            nre='N Reverse Edges' tpr='True Positive Rate';
    run;
%mend;

%macro dagTrials(sTrial,eTrial,nNodes,nEdges,nObs,tblEval);
    %do simId = &sTrial. %to &eTrial.;
        %put "Simulation &simId.";
        %dagTrial(&simId.,&nNodes.,&nEdges.,&nObs.,&tblEval.);
    %end;
    %dagPrint(&tblEval.);
%mend;

```

First, the 100-variable, 600-edge DAG case is checked using the following code:

```

%let nNodes = 100;
%let nEdges = 600;
%let nObs = 10000;
%let tblEval = evalSparse;
%dagTrials(1,30,&nNodes.,&nEdges.,&nObs.,&tblEval.);

```

The results are shown in [Output 6.1.1](#). Because the proper significance level is chosen (in this case, 10^{-6} or 10^{-8}), the SHD decreases to zero for all 30 trials, which means that the true 100-variable DAGs in all 30 trials are perfectly discovered and the TOP algorithm reaches 100% accuracy. Such results are not seen in any algorithms that are studied by Yu et al. (2021), who also perform the experiments on the 100-variable, 600-edge DAGs.

Output 6.1.1 Accuracy for 100-Variable, 600-Edge DAG Structure Learning

Significance Level	Type	Structural Hamming Distance	N Missing Edges	N Extra Edges	N Reverse Edges	True Positive Rate
0.00000001	Mean	0.00	0.00	0.00	0.00	1.00
0.00000001	Std.	0.00	0.00	0.00	0.00	0.00
0.00000100	Mean	0.00	0.00	0.00	0.00	1.00
0.00000100	Std.	0.00	0.00	0.00	0.00	0.00
0.00010000	Mean	0.37	0.00	0.37	0.00	1.00
0.00010000	Std.	0.49	0.00	0.49	0.00	0.00
0.01000000	Mean	43.60	0.00	43.60	0.00	1.00
0.01000000	Std.	6.09	0.00	6.09	0.00	0.00
0.10000000	Mean	439.10	0.00	439.10	0.00	1.00
0.10000000	Std.	24.65	0.00	24.65	0.00	0.00
1.00000000	Mean	4350.00	0.00	4350.00	0.00	1.00
1.00000000	Std.	0.00	0.00	0.00	0.00	0.00

Second, the number of edges is increased to 2,400. The SAS code is as follows:

```
%let nNodes = 100;
%let nEdges = 2400;
%let nObs = 10000;
%let tblEval = evalMedium;
%dagTrials(1,30,&nNodes.,&nEdges.,&nObs.,&tblEval.);
```

The results are shown in [Output 6.1.2](#). Surprisingly, because the significance level is set to 10^{-6} or 10^{-8} , the accuracy of the TOP algorithm reaches 100% again.

Output 6.1.2 Accuracy for 100-Variable, 2,400-Edge DAG Structure Learning

Significance Level	Type	Structural Hamming Distance	N Missing Edges	N Extra Edges	N Reverse Edges	True Positive Rate
0.00000001	Mean	0.00	0.00	0.00	0.00	1.00
0.00000001	Std.	0.00	0.00	0.00	0.00	0.00
0.00000100	Mean	0.00	0.00	0.00	0.00	1.00
0.00000100	Std.	0.00	0.00	0.00	0.00	0.00
0.00010000	Mean	0.13	0.00	0.13	0.00	1.00
0.00010000	Std.	0.35	0.00	0.35	0.00	0.00
0.01000000	Mean	25.87	0.00	25.87	0.00	1.00
0.01000000	Std.	4.83	0.00	4.83	0.00	0.00
0.10000000	Mean	252.60	0.00	252.60	0.00	1.00
0.10000000	Std.	16.49	0.00	16.49	0.00	0.00
1.00000000	Mean	2550.00	0.00	2550.00	0.00	1.00
1.00000000	Std.	0.00	0.00	0.00	0.00	0.00

Finally, the largest possible number of edges, 4,950 edges, for a 100-variable DAG is tried. The SAS code is as follows:

```
%let nNodes = 100;
%let nEdges = 4950;
%let nObs = 10000;
%let tblEval = evalFull;
%dagTrials(1,30,&nNodes.,&nEdges.,&nObs.,&tblEval.);
```

The results are shown in [Output 6.1.3](#). Because the significance level is chosen as 0.10 or 0.01, the TOP algorithm reaches 100% accuracy again. In this extreme case, even if other significance levels are chosen, the accuracy is still very high.

Output 6.1.3 Accuracy for 100-Variable, 4,950-Edge DAG Structure Learning

Significance Level	Type	Structural Hamming Distance	N Missing Edges	N Extra Edges	N Reverse Edges	True Positive Rate
0.00000001	Mean	1.60	1.60	0.00	0.00	1.00
0.00000001	Std.	1.45	1.45	0.00	0.00	0.00
0.00000100	Mean	0.27	0.27	0.00	0.00	1.00
0.00000100	Std.	0.58	0.58	0.00	0.00	0.00
0.00010000	Mean	0.07	0.07	0.00	0.00	1.00
0.00010000	Std.	0.25	0.25	0.00	0.00	0.00
0.01000000	Mean	0.00	0.00	0.00	0.00	1.00
0.01000000	Std.	0.00	0.00	0.00	0.00	0.00
0.10000000	Mean	0.00	0.00	0.00	0.00	1.00
0.10000000	Std.	0.00	0.00	0.00	0.00	0.00
1.00000000	Mean	0.00	0.00	0.00	0.00	1.00
1.00000000	Std.	0.00	0.00	0.00	0.00	0.00

In all three cases, the TPR is always 100%, which means that in all 90 trials, the true directed edges are always found. When you run the code in this example on a 2,160-CPU grid, each trial takes only a few seconds. Note that the TOP algorithm is not an exact algorithm. Although in this example the TOP algorithm always reaches 100% accuracy for some chosen significance levels, it is not guaranteed that the TOP algorithm can reach 100% accuracy for other data sets. However, this example does show how fast, and especially how accurate, the TOP algorithm is.

Example 6.2: Learning a Large DAG by Using the MCV Algorithm

This example illustrates the accuracy and speed of the MCV algorithm, which is available in the CAUSAL-DISCOVERY procedure, by using a DAG that contains 1,000 variables and 6,000 edges.

In the following SAS code, the SIMULATE statement first simulates the DAG and then generates a 10,000-observation data set based on the simulated DAG. Then the LEARN statement estimates the DAG according to the simulated data set by using the MCV algorithm. Finally, the EVALUATE statement evaluates the accuracy of the estimated DAG.

```

proc causaldiscovery ;
  var x1 - x1000;
  simulate out=mylib.sdag outdata=mylib.outdata / nEdges=6000 nObs=10000
    parm(dist=uniform(lb=-0.75 ub=0.75 excllb=-0.4 exclub=0.4)) seed=123
    outparm = mylib.outparm outorder=mylib.outorder;

  learn outdag=mylib.outdag /
    algorithm=mcv initmethod=data
    alpha=(0.1 0.01 0.0001 0.000001 0.00000001);

  evaluate /out=mylib.oeval;
run;

```

The algorithm information is shown in [Output 6.2.1](#).

Output 6.2.1 Algorithm Information
The CAUSALDISCOVERY Procedure

Algorithm Information	
Algorithm	Minimizing Conditional Variance
Initialization Method	Data
Maximum Iterations	200
Parallel	Yes
Seed	1

The following statements print the accuracy metrics, which are shown in [Output 6.2.2](#):

```

proc print data=mylib.oeval noobs label;
  format alpha f10.8;
  format shd nme nee nre tpr f7.2;
  label alpha='Significance Level'
    shd='Structural Hamming Distance'
    nme='N Missing Edges' nee='N Extra Edges'
    nre='N Reverse Edges' tpr='True Positive Rate';
run;

```

Output 6.2.2 Accuracy of 1,000-Variable, 6,000-Edge DAG Structure Learning

Significance Level	Structural Hamming Distance	N Missing Edges	N Extra Edges	N Reverse Edges	True Positive Rate
0.00000001	0.00	0.00	0.00	0.00	1.00
0.00000100	1.00	0.00	1.00	0.00	1.00
0.00010000	43.00	0.00	43.00	0.00	1.00
0.01000000	5040.00	0.00	5040.00	0.00	1.00
0.10000000	49217.0	0.00	49217.0	0.00	1.00
1.00000000	493500	0.00	493500	0.00	1.00

The MCV algorithm has a 100% accuracy for a significance level of 10^{-8} , and the true positive rate is 100%. The algorithm is very fast, taking only a few seconds when you run the code in this example on one CPU.

Example 6.3: Using Causal Discovery on Panel Data with Fixed Effects

This example illustrates how to use the CAUSALDISCOVERY procedure to learn and evaluate a DAG that is generated from panel data that have individual fixed effects. The covariates of the data are denoted as x , and the group dummies are denoted as gn . The structural Hamming distance (SHD) and true positive rate (TPR) are compared in two cases:

- Case 1: using x variables as nodes of the graph
- Case 2: using x variables as nodes of the graph and gn variables as the root nodes of the graph

The first macro generates the panel data that have individual fixed effects as follows:

```
%macro generate_ds(dsname=);

    /* ngn groups, nT periods, and nNodes covariates */
    /* x(it) is generated by x(i1), ..., x(i, t-1), and gn(i) */
    /* for t=2, ..., t=nT */

    %put "Start generating data set &dsname..";
    %let seed = 54321;      /* Random seed */
    %let mean_shift = 1;    /* Increase mean */
    %let var_scale = 1;     /* Increase variance */

    data mylib.&dsname;
        call streaminit(&seed); /* Initialize RNG once */
        array x[&nNodes];      /* x1 to x&nNodes. */
        keep x1-x&nNodes gn t %do i=1 %to %eval(&ngn); gn&i %end;;

        do gn = 1 to &ngn;
            do t = 1 to &nT;

                /* Create group dummies */
                %do i = 1 %to %eval(&ngn);
                    gn&i = (gn = &i);
                %end;

                /* Generate x1 to x&nNodes. with increasing dependencies */
                do i = 1 to &nNodes;
                    /* Scaled noise and shifted mean */
                    x[i] = &var_scale * rannorm(1) + &mean_shift;

                    /* Add dependency on previous x variables */
                    if i > 1 then do;
                        do j = 1 to (i-1);
                            sign = (-1)**(j); /* Alternates: -1, 1, -1, 1, ... */
                            /* Use sqrt scaling for slower growth */
                            x[i] + (&var_scale * (0.1 * sqrt(j))) * sign * x[j];
                        end;
                    end;

                    /* Add dependency on gn with increasing strength */
```

```

            x[i] + (&var_scale * 0.05 * i) * gn;
        end;

        output;
    end;
end;
run;

%mend;

```

You determine the true DAG from the true topological order by using the IML procedure as follows:

```

%macro create_dag(dagname=, topo_order=);
    proc iml;
        p = &nNodes;
        var_id = T(1:p);

        /* Get sorted indices for topological order */
        call sortndx(idx,&topo_order.,1);
        topo_order2 = var_id[idx,];

        /* Build full W (complete DAG for this order) */
        W = j(p,p,0);

        do j=2 to p;
            do r=1 to j-1;
                W[topo_order2[r],topo_order2[j]] = 1;
            end;
        end;

        x_vars = "x1":"x&nNodes.";
        W2 = T(1:p) || j(p,1,1) || W;
        x_vars2 = "rowId" || 'alpha' || x_vars;

        create &dagname from W2[colname=x_vars2];
        append from W2;
        close &dagname;
    quit;

    data mylib.&dagname;
        set &dagname;
    run;
%mend;

```

The following macro runs PROC CAUSALDISCOVERY for each of the two preceding cases:

```

%macro causaldiscovery(dsname=);

    %put "Start running PROC CAUSALDISCOVERY with only x as nodes
    on data set &dsname..";

    /* Two cases:
    1. x variables are used as nodes
    2. x variables are used as nodes and
       group dummies are used as root nodes
    */

```

```

*/

/* Case 1: Only x variables are used as nodes in the analysis */
* learn the DAG structure;
ods output EstFullAdjMat = mylib.&dsname._PROC_EstFullAdjMat
      EstAdjMatrices = mylib.&dsname._PROC_EstAdjMatrices
      NObs = mylib.&dsname._PROC_NObs
      TopoOrders = mylib.&dsname._PROC_TopoOrders
      AlgoInfo = mylib.&dsname._PROC_AlgoInfo;
proc causaldiscovery;
  var %do i=1 %to (&nNodes); x&i %end;;
  learn data=mylib.&dsname. outdag=mylib.&dsname._PROC_outdag /
    nonparallel maxiter=200
    initmethod=data alpha=(0.1 0.01 0.0001 0.000001 0.00000001)
    outiter=mylib.&dsname._PROC_outiter out=mylib.&dsname._PROC_oest
    outpath=mylib.&dsname._PROC_opath;
run;

%put "Start running PROC CAUSALDISCOVERY with group as root nodes
      on data set &dsname..";
/* Case 2: The group dummies are used as root nodes in the analysis */
* learn the DAG structure;
ods output EstFullAdjMat = mylib.&dsname._PROC_gn_EstFullAdjMat
      EstAdjMatrices = mylib.&dsname._PROC_gn_EstAdjMatrices
      NObs = mylib.&dsname._PROC_gn_NObs
      TopoOrders = mylib.&dsname._PROC_gn_TopoOrders
      AlgoInfo = mylib.&dsname._PROC_gn_AlgoInfo;
proc causaldiscovery;
  var %do i=1 %to (&nNodes); x&i %end;;
  rootvar %do i=1 %to &ngn; gn&i %end;;
  learn data=mylib.&dsname.
    outdag=mylib.&dsname._PROC_gn_outdag /
    nonparallel maxiter=200
    initmethod=data alpha=(0.1 0.01 0.0001 0.000001 0.00000001)
    outiter=mylib.&dsname._PROC_gn_outiter
    out=mylib.&dsname._PROC_gn_oest
    outpath=mylib.&dsname._PROC_gn_opath;
run;
/* note that all the group dummies gn1-gn&ngn. are included
because there is no intercept in the model */

%put "Finished running PROC CAUSALDISCOVERY on data set &dsname..";
%mend;

```

The following macro evaluates the resulting DAGs from both cases against the true DAG:

```

%macro evaluate_dag(dsname=);

  %put "Start evaluating DAGs for data set &dsname..";

  /* Prepare DAGs for evaluations */

  /* Create the true DAG */
  %let &dsname._true_topo = T(1:&nNodes.);

```

```

/* True topological order is natural order by DGP */
%create_dag(dagname=&dsname._true_dag,
  topo_order=&&&dsname._true_topo.);

/* Extract the outdag where alpha=1 when only x variables are
used as nodes */
data mylib.&dsname._PROC_outdag_eval;
  set mylib.&dsname._PROC_outdag(where=(alpha=1));
run;

/* Extract the outdag where alpha=1 when gn are used as root nodes */
data mylib.&dsname._PROC_gn_outdag_eval;
  set mylib.&dsname._PROC_gn_outdag(where=(alpha=1));
run;

/* Extract the topological order for the x variables only, rerank it,
and store in a macro */
proc sql noprint;
  create table temp as
  select monotonic() as id, finalOrder as value
  from mylib.&dsname._PROC_gn_TopoOrders (obs=&nNodes);

  create table ranked as
  select a.value, a.id,
  (select count(*) from temp b where b.value < a.value) + 1 as rank
  from temp a;

  select rank
  into :&dsname._PROC_gn_TopoOrders separated by ' '
  from ranked
  order by id;

  drop table temp, ranked;
quit;

/* Create the estimated adjacency matrix for the x variables only
when running PROC CAUSALDISCOVERY with both x variables and group
dummies included as nodes */
%create_dag(dagname=&dsname._PROC_gn_outdag_eval,
  topo_order=T({&&&dsname._PROC_gn_TopoOrders.}));
/* note: need to transform &&&dsname._PROC_gn_TopoOrders. to a
numeric column vector*/

/* Evaluate the estimated DAG from PROC CAUSALDISCOVERY when
only x variables are used as nodes */
proc causaldiscovery;
  var %do i=1 %to (&nNodes); x&i %end;;
  evaluate estdag = mylib.&dsname._PROC_outdag_eval
    truedag = mylib.&dsname._true_dag /
    out=mylib.&dsname._PROC_eval;
run;

/* Evaluate the estimated DAG from PROC CAUSALDISCOVERY when
group dummies are used as root nodes */

```

```

proc causaldiscovery;
  var %do i=1 %to (&nNodes); x&i %end;;
  evaluate estdag = mylib.&dsname._PROC_gn_outdag_eval
    truedag = mylib.&dsname._true_dag /
    out=mylib.&dsname._PROC_gn_eval;
run;

%mend;

```

Finally, the following macro collects and prints the results:

```

%macro print_outputs(dsname=);

  ods html5 close; /* close any open */
  ods html5 path="~/results_causex3" (url=none)
    file="&dsname._results.html"
    gtitle gfootnote;

  title3 "&dsname: Evaluation of Estimated DAG: Case 1";
  proc print data=mylib.&dsname._PROC_eval noobs;
  run;

  title3 "&dsname: Evaluation of Estimated DAG: Case 2";
  proc print data=mylib.&dsname._PROC_gn_eval noobs;
  run;

  ods html5 close;

%mend;

```

Now that the macros have been defined, the body of the example program is as follows:

```

%let ngn = 10; /* number of groups */
%let nT = 1000; /* number of time periods */
%let dsname = ds1_1_a;
%let nNodes = 20; /* number of nodes */
%let max_iter = 200; /* Set the maximum iterations */

/* Suppress display (but still build ODS OUTPUT data sets) */
ods exclude all;
options nonotes nosource;

%generate_ds(dsname=&dsname.);
%causaldiscovery(dsname=&dsname.);
%evaluate_dag(dsname=&dsname.);

/* Re-enable output for final reporting */
ods exclude none;
options notes source;
%print_outputs(dsname=&dsname.);

proc printto; run;

```

The results from this program are shown in [Output 6.3.1](#). The tables has the following output columns: confidence level (alpha), structural Hamming distance (shd), number of missing edges (nme), number of

extra edges (nee), number of reversed edges (nre), and true positive rate (tpr).

In case 1, because you treat only the x variables as nodes, the estimation of the DAG shows deterioration. If you also include the group dummies in the analysis, the true DAG is found.

Output 6.3.1 Evaluation of Estimated DAG from PROC CAUSALDISCOVERY

ds1_1_a: Evaluation of Estimated DAG: Case 1

alpha	shd	nme	nee	nre	tpr
1	63	0	0	63	0.66842

ds1_1_a: Evaluation of Estimated DAG: Case 2

alpha	shd	nme	nee	nre	tpr
1	1	0	0	1	0.99474

Overview: CCDM Procedure

In many loss modeling applications, you analyze the loss events by modeling the severity (magnitude) of loss and the frequency (count) of loss separately. The primary goal of creating these models is to estimate the aggregate loss—that is, the total loss that occurs over a period of time for which the frequency model is applicable. For example, an insurance company might want to assess the expected and worst-case losses for a particular business line, such as automobile insurance, over an entire year by using the models for the number of losses in a year and the severity of each loss. A bank might want to assess the value-at-risk (VaR), a measure of the worst-case loss, for a portfolio of assets by using the frequency and severity models for each asset type.

Severity of loss and frequency of loss are random variables, so the aggregate loss is also a random variable. Instead of preparing a point estimate of the expected aggregate loss, it is better to estimate its probability distribution, because this enables you to infer various aspects of the aggregate loss, such as measures of location, scale (variability), and shape, in addition to percentiles. For example, the VaR that banks or insurance companies use to compute regulatory capital requirements is usually the estimate of the 97.5th or 99th percentile from the aggregate loss distribution.

Let N represent the frequency random variable for the number of loss events that occur in the time period of interest. Let X represent the severity random variable for the magnitude of one loss event. Then, the aggregate loss S is defined as

$$S = \sum_{j=1}^N X_j$$

The goal is to estimate the probability distribution of S . Let $F_X(x)$ denote the cumulative distribution function (CDF) of X , let $F_X^{*n}(x)$ denote the n -fold convolution of the CDF of X , and let $\Pr(N = n)$ denote the probability of seeing n losses as per the frequency distribution. The CDF of S is theoretically computable as

$$F_S(s) = \sum_{n=0}^{\infty} \Pr(N = n) \cdot F_X^{*n}(x)$$

This probability distribution model of S , characterized by the CDF $F_S(s)$, is referred to as a *compound distribution model* (CDM). The CCDM procedure computes an estimate of the CDM by using the distribution models of X and N .

Direct computation of F_S is usually a difficult task because of the need to compute the n -fold convolution. Klugman, Panjer, and Willmot (1998, Ch. 4) suggest some relatively efficient recursion and inversion methods for certain combinations of severity and frequency distributions. However, those methods assume that distributions of N and X are fixed and all X s are identically distributed. When the distributions of X and N are conditional on external factors (regressors), each set of regressor values results in a different distribution. So you must repeat the recursion and inversion methods for each combination of regressor values, and this repetition makes these methods prohibitively expensive. PROC CCDM instead estimates the compound distribution by using a Monte Carlo simulation method, which can use all available computational resources to generate a sufficiently large, representative sample of the compound distribution while accommodating the dependence of distributions of X and N on external factors. Conceptually, the simulation method works as follows:

1. Use the specified frequency model to draw a value N , which represents the number of loss events.

2. Use the specified severity model to draw N values, each of which represents the magnitude of loss for each of the N loss events.
3. Add the N severity values from step 2 to compute the aggregate loss S as

$$S = \sum_{j=1}^N X_j$$

This forms one sample point of the CDM.

Steps 1 through 3 are repeated M times, where M is a number that you specify, to obtain the representative sample of the CDM. PROC CCDM analyzes this sample to compute empirical estimates of various summary statistics of the compound distribution such as the mean, variance, skewness, and kurtosis in addition to percentiles such as the median, the 95th percentile, the 99th percentile, and so on. You can also use PROC CCDM to write the entire simulated sample to an output data table.

The simulation process gets more complicated when the frequency and severity models contain regression effects. The CDM is then conditional on the values of regressors. The simulation process essentially becomes a scenario analysis, because you need to specify the expected values of the regressors that together represent the scenario for which you want to estimate the CDM. PROC CCDM enables you to specify an input data table that contains the scenario. If you are modeling a group of entities together (such as a portfolio of multiple assets or a group of insurance policies), and each entity has a different set of characteristics, then the scenario consists of more than one observation, and each observation corresponds to a different entity. PROC CCDM enables you to specify such a group scenario in the input data table and creates a realistic simulation of loss events that each entity can generate.

PROC CCDM accepts the severity model of X as estimated by the SEVSELECT procedure, and it accepts the frequency model of N as estimated by the CNTSELECT procedure. Both the SEVSELECT and CNTSELECT procedures are part of SAS Econometrics software. Both procedures allow models of X and N to be conditional on external factors (regressors). In particular, you can model the severity distribution such that its scale parameter depends on severity regressors, and you can model the frequency distribution such that its mean depends on frequency regressors. The frequency model can also be a zero-inflated model. PROC CCDM uses the estimates of model parameters and the values of severity and frequency regressors to estimate the compound distribution model.

PROC CCDM also enables you to specify externally simulated counts. This is useful if you have an empirical frequency model or if you estimate the frequency model by using a method other than using PROC CNTSELECT. To specify an external count model, you create a data table that contains M replications of counts that are randomly drawn from your frequency model. For each of the replications, in step 1 of the simulation, PROC CCDM uses the count N that is associated with that replication in the count data table. If the severity model contains regression effects, then you can specify the scenario to analyze by specifying the severity regressor data for each of the M replications in the same count data table.

If the estimates of the parameters of your severity and frequency models have uncertainty associated with them, and they usually do, then you can use PROC CCDM to conduct parameter perturbation analysis to assess the effect of the uncertainty in parameter estimates on the estimates of CDM. If you request that P perturbed samples be generated, then the parameter set is perturbed P times, and each time PROC CCDM makes a random draw from either the univariate normal distribution of each parameter or the multivariate normal distribution over all parameters. For each of the P perturbed parameter sets, a full compound distribution sample is simulated and summarized. This process yields P estimates for each summary statistic

and percentile, which are then used to provide you with estimates of the location and variability of each summary statistic and percentile.

You can also use PROC CCDM to compute the distribution of an aggregate *adjusted* loss. For example, in insurance applications, you might want to compute the distribution of the amount paid in a particular time period after applying adjustments such as the deductible and the policy limit to each individual loss. PROC CCDM enables you to specify SAS programming statements to adjust each severity value. If X_j^d represents the d th adjusted severity value, then PROC CCDM computes S^d , the d th aggregate adjusted loss, as

$$S^d = \sum_{j=1}^N X_j^d$$

You can define and analyze as many adjusted losses as you want in one PROC CCDM step. All the analyses that PROC CCDM conducts for the aggregate unadjusted loss, including scenario analysis and parameter perturbation analysis, are also conducted for each aggregate adjusted loss. This gives you a comprehensive picture of the compound distribution model for each adjusted loss.

PROC CCDM is the next-generation version of PROC HPCDM. It requires SAS Cloud Analytic Services (CAS) in order to run. Because PROC CCDM is a next-generation high-performance analytical procedure, it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the

CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the mysess session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CCDM Procedure

This section outlines the use of the CCDM procedure to fit compound distribution models. The examples are intended as a gentle introduction to some of the features of the procedure.

Estimating a Simple Compound Distribution Model

This example illustrates the simplest use of PROC CCDM. Assume that you are an insurance company that has used its historical data about the number of losses per year and the severity of each loss to determine that the Poisson distribution is the best distribution for the loss frequency and that the gamma distribution is the best distribution for the severity of each loss. Now, you want to estimate the distribution of an aggregate loss to determine the worst-case loss that your policyholders can incur in a year. In other words, you want to estimate the compound distribution of $S = \sum_{i=1}^N X_i$, where the loss frequency, N , follows the fitted Poisson distribution and the severity of each loss event, X_i , follows the fitted gamma distribution.

To illustrate, let the historical count and severity data be stored in the data sets Work.ClaimCount and Work.ClaimSev, respectively. The following two DATA steps simulate a frequency sample from a Poisson distribution and a severity sample from the gamma distribution, respectively:

```
/* Simulate data for an intercept-only Poisson count model */
data claimcount(keep=numLosses);
  call streaminit(12345);
  label numLosses='Number of Loss Events in a Year';
  Lambda = 2;
  do n = 1 to 500;
    numLosses = rand('POISSON', Lambda);
    output;
  end;
run;

/* Simulate data for a gamma severity model */
data claimsev(keep=lossValue);
  call streaminit(67890);
  label lossValue='Severity of a Loss Event';
  Theta = 1000;
  Alpha = 2;
  do n = 1 to 500;
```

```

        lossValue = quantile('Gamma', rand('UNIFORM'), Alpha, Theta);
        output;
    end;
run;

```

You can load the data sets `Work.ClaimCount` and `Work.ClaimSev` into data tables in your CAS session by using your CAS engine libref with the following DATA steps:

```

/* Load the data */
data mylib.claimcount;
    set claimcount;
run;
data mylib.claimsev;
    set claimsev;
run;

```

These statements assume that your CAS engine libref is named `mylib`, as in the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 174, but you can substitute any appropriately defined CAS engine libref.

To create model parameter estimates in a format that PROC CCDM can use, you need to use the following PROC CNTSELECT and PROC SEVSELECT steps to fit and store the parameter estimates of the frequency and severity models:

```

/* Fit an intercept-only Poisson count model and
   write estimates to an item store */
proc cntselect data=mylib.claimcount store=mylib.countStorePoisson;
    model numLosses= / dist=poisson;
run;

/* Fit severity models and write estimates to a data table */
proc sevselect data=mylib.claimsev criterion=aicc
    outest=mylib.sevest covout;
    loss lossValue;
    dist _predefined_;
run;

```

The `STORE=` option in the PROC CNTSELECT statement saves the count model information, including the parameter estimates, in the item store `mylib.CountStorePoisson`. An item store contains the model information in a binary format that cannot be modified after it is created. You can examine the contents of an item store that is created by a PROC CNTSELECT step by using the `VIEWSTORE` statement in another PROC CNTSELECT step. (For more information, see Chapter 10, “[CNTSELECT Procedure](#).”)

The `OUTEST=` option in the PROC SEVSELECT statement stores the estimates of all the fitted severity models in the data table `mylib.SevEst`. You can verify that the best severity model that the PROC SEVSELECT step chooses is the gamma distribution model.

You can now submit the following PROC CCDM step to simulate an aggregate loss sample of size 10,000 by specifying the count model’s item store in the `COUNTSTORE=` option and the severity model’s data table of estimates in the `SEVERITYEST=` option:

```

/* Simulate and estimate Poisson-gamma compound distribution model */
proc ccdm countstore=mylib.countStorePoisson severityest=mylib.sevest
    seed=13579 nreplicates=10000 plots=(edf density)
    print=(summarystatistics percentiles);
    severitymodel gamma;

```

```

output out=mylib.aggregateLossSample samplevar=aggloss;
outsum out=mylib.aggregateLossSummary mean stddev skewness kurtosis
      p01 p05 p95 p995=var pctlpts=90 97.5;
run;

```

The SEVERITYMODEL statement requests that an aggregate sample be generated by compounding only the gamma distribution and the frequency distribution. Specifying the SEED= value helps you get an identical sample each time you execute this step, provided that you use the same execution environment. In the single-machine mode of execution, the execution environment is the combination of the operating environment and the number of threads that are used for execution. In distributed computing mode, the execution environment is the combination of the operating environment, the number of worker nodes, and the number of threads that are used for execution on each worker node.

Upon completion, PROC CCDM creates the two output data tables that you specify in the OUT= options in the OUTPUT and OUTSUM statements. The data table mylib.AggregateLossSample contains 10,000 observations such that the value of the variable AggLoss in each observation represents one possible aggregate loss value that you can expect to see in one year. Together, the set of the 10,000 values of AggLoss represents one sample of compound distribution. PROC CCDM uses this sample to compute the empirical estimates of various summary statistics and percentiles of the compound distribution. The data table mylib.AggregateLossSummary contains the estimates of mean, standard deviation, skewness, and kurtosis that you specify in the OUTSUM statement. It also contains the estimates of the 1st, 5th, 90th, 95th, 97.5th, and 99.5th percentiles that you specify in the OUTSUM statement. The value-at-risk (VaR) is an aggregate loss value such that there is a very low probability that an observed aggregate loss value exceeds the VaR. One of the commonly used probability levels to define VaR is 0.005, which makes the 99.5th percentile an empirical estimate of VaR. Hence, the OUTSUM statement of this example stores the 99.5th percentile in a variable named VaR. VaR is one of the widely used measures of worst-case risk.

Some of the default output and some of the output that you have requested by specifying the PRINT= option are shown in [Figure 7.1](#).

Figure 7.1 *continued*

Sample Percentiles	
Percentile	Value
1	0
5	0
25	1345.4
50	3360.3
75	5915.1
90	8691.7
95	10602.8
97.5	12294.1
99	14720.1
99.5	16055.7
Percentile Method = 5	

The “Sample Summary Statistics” table indicates that for the given parameter estimates of the Poisson frequency and gamma severity models, you can expect to see a mean aggregate loss and a median aggregate loss in a year. The “Sample Percentiles” table indicates that there is a 0.5% chance that the aggregate loss exceeds the 99.5th percentile, which is the VaR estimate, and a 2.5% chance that the aggregate loss exceeds the 97.5th percentile. These summary statistics and percentile estimates provide a quantitative picture of the compound distribution.

You can also visually analyze the compound distribution by examining the plots that PROC CCDM creates when you specify the PLOTS= option. The first plot in [Figure 7.2](#) shows the empirical distribution function (EDF), which is a nonparametric estimate of the cumulative distribution function (CDF). The second plot shows the histogram and the kernel density estimate, which are nonparametric estimates of the probability density function (PDF).

Figure 7.2 Nonparametric CDF and PDF Plots of the Poisson-Gamma Compound Distribution

Figure 7.2 *continued*

The plots confirm the right skew that is indicated by the estimate of skewness in Figure 7.1 and a relatively fat tail, which is indicated by comparing the maximum and the 99.5th percentiles in Figure 7.1.

Analyzing the Effect of Parameter Estimate Uncertainty on the Compound Distribution

Continuing with the previous example, note that you have fitted the frequency and severity models by using the historical data. Even if you choose the best-fitting models, the true underlying models are not known exactly. This fact is reflected in the uncertainty that is associated with the estimates of your model parameters. Any compound distribution estimate that you compute by using these uncertain parameter estimates is inherently uncertain. You can request that PROC CCDM perform parameter perturbation analysis; this analysis assesses the effect of the uncertainty in parameter estimates on the estimates of the compound distribution by simulating multiple samples, each of which uses parameters that are randomly perturbed from their mean estimates.

The following PROC CCDM step adds the NPerturbedSamples= option to the PROC CCDM statement to perform perturbation analysis and the PRINT=PERTURBSUMMARY option to display a summary of the perturbation analysis:

```
/* Perform parameter perturbation analysis of
   the Poisson-gamma compound distribution model */
proc ccdm countstore=mylib.countStorePoisson severityest=mylib.sevest
  seed=13579 nreplicates=10000 nperturbedsamples=30
  print (only)=(perturbsummary);
  severitymodel gamma;
  output out=mylib.aggregateLossSample samplevar=aggloss;
  outsum out=mylib.aggregateLossSummary mean stddev skewness kurtosis
    p01 p05 p95 p995=var pctlpts=90 97.5;
run;
```

The data table mylib.AggregateLossSummary contains the specified summary statistics and percentiles for all 30 perturbed samples. You can identify a perturbed sample by the value of the variable `_DRAWID_`. Figure 7.3 shows the first few observations of the data table mylib.AggregateLossSummary. For the first observation, the value of `_DRAWID_` is 0, which represents an unperturbed sample—that is, the aggregate sample that is simulated without perturbing the parameters from their means.

1.22101	1.92094	0	0	8411.36	10455.43	12313.91	16456.85

The PRINT=PERTURBSUMMARY option in the preceding PROC CCDM step produces the “Sample Perturbation Analysis” and “Sample Percentile Perturbation Analysis” tables shown in Figure 7.4. The tables

show the mean aggregate loss and the standard error of the mean. If you want to use the VaR estimate to determine the amount of reserves that you need to maintain to cover the worst-case loss, then you should consider not only the mean estimate of the 99.5th percentile, but also the standard error to account for the effect of uncertainty in your frequency and severity parameter estimates.

Scenario Analysis

The distributions of loss frequency and loss severity often depend on exogenous variables (regressors). For example, the number of losses and the severity of each loss that an automobile insurance policyholder incurs might depend on the characteristics of both the policyholder and the vehicle. When you fit frequency and severity models, you need to account for the effects of such regressors on the probability distributions of the counts and severity. The CNTSELECT procedure enables you to model regression effects on the mean of the count distribution, and the SEVSELECT procedure enables you to model regression effects on the scale parameter of the severity distribution. When you use these models to estimate the compound distribution model of the aggregate loss, you need to specify a set of values for all the regressors, which represents the state of the world for which the simulation is conducted. This is referred to as the what-if or scenario analysis.

Suppose that you, as an automobile insurance company, have postulated that the distribution of the loss event frequency depends on five regressors (external factors): age of the policyholder, gender, type of car, miles driven annually, and policyholder's education level. Further, the distribution of the severity of each loss depends on three regressors: type of car, safety rating of the car, and annual household income of the policyholder (which can be thought of as a proxy for the luxury level of the car). Note that the frequency model regressors and severity model regressors can be different, as illustrated in this example.

Let these regressors be recorded, respectively, in the variables Age (scaled by a factor of 1/50), Gender (1: female, 2: male), CarType (1: sedan, 2: sport utility vehicle), AnnualMiles (scaled by a factor of 1/5,000), Education (1: high school graduate, 2: college graduate, 3: advanced degree holder), CarSafety (scaled to be between 0 and 1, the safest being 1), and Income (scaled by a factor of 1/100,000).

To illustrate, the following DATA steps simulate and record the historical data about the number of losses that various policyholders incur in a year in the variable NumLoss of the data table mylib.LossCounts, and the severity of each loss in the variable LossAmount of the data table mylib.Losses:

```
/* Simulate data for losses that several policyholders incur in a year */
data losses(keep=policyholderId age gender carType annualMiles
             education carSafety income nolos lossamount);
  call streaminit(12345);
  array cx{5} age gender carType annualMiles education;
  array cbeta{6} _TEMPORARY_ (1 -0.75 1 0.6 -1 -0.25);

  array sx{3} carType carSafety income;
  array sbeta{4} _TEMPORARY_ (3.5 1.5 -0.8 0.6);

  alpha = 1/3; theta = 1/alpha;
  Sigma = 1;
  do policyholderId=1 to 5000;
    /* simulate policyholder and vehicle attributes */
    age = MAX(int(rand('NORMAL', 35, 15)),16)/50;

    if (rand('UNIFORM') < 0.5) then gender = 1; * female;
    else gender = 2; * male;

    if (rand('UNIFORM') < 0.7) then carType = 1; * sedan;
    else carType = 2; * SUV;

    annualMiles = MAX(1000, int(rand('NORMAL', 12000, 5000)))/5000;
```

```

educationLevel = rand('UNIFORM');
if (educationLevel < 0.5) then education = 1; *high school graduate;
else if (educationLevel < 0.85) then education = 2; *college graduate;
else education = 3; *advanced degree;

carSafety = rand('UNIFORM'); /* scaled to be between 0 & 1 */

income = MAX(15000,int(rand('NORMAL', education*30000, 50000)))/100000;

/* simulate number of losses incurred by this policyholder */
cxbeta = cbeta(1);
do i=1 to dim(cx);
    cxbeta = cxbeta + cx(i) * cbeta(i+1);
end;
Mu = exp(cxbeta);
p = theta/(Mu+theta);
numloss = rand('NEGB',p,theta);

/* simulate severity of each loss */
if (numloss > 0) then do;
    noloss = 0;
    do iloss=1 to numloss;
        Mu = sbeta(1);
        do i=1 to dim(sx);
            Mu = Mu + sx(i) * sbeta(i+1);
        end;
        lossamount = exp(Mu) * rand('LOGNORMAL')**Sigma;
        output;
    end;
end;
else do;
    noloss = 1;
    lossamount = .;
    output;
end;
end;
run;

/* Aggregate number of annual loss events for each policyholder */
data losscounts(keep=age gender carType annualMiles education numloss);
set losses;
by policyholderId;
retain numloss 0;
if (noloss ne 1) then
    numloss = numloss + 1;
if (last.policyholderId) then do;
    output;
    numloss = 0;
end;
run;

/* Load the data */
data mylib.losses;

```

```

    set losses;
run;
data mylib.losscounts;
    set losscounts;
run;

```

Note that the last two DATA steps in the previous program load the local SAS data sets Work.LossCounts and Work.Losses into the data tables mylib.LossCounts and mylib.Losses, respectively, in your CAS session that is associated with the mylib CAS engine libref.

The following PROC CNTSELECT step fits the count regression model and stores the fitted model information in the item store mylib.CountregModel:

```

/* Fit negative binomial frequency model for the number of losses */
proc cntselect data=mylib.losscounts store=mylib.countregmodel;
    model numloss = age gender carType annualMiles education / dist=negbin;
run;

```

You can examine the parameter estimates of the count model that are stored in the item store mylib.CountregModel by submitting the following statements:

```

/* Examine the parameter estimates for the model in the item store */
proc cntselect data=mylib.losscounts;
    viewstore / instore=mylib.countregmodel finalestimates;
run;

```

The “Parameter Estimates” table that is displayed by the SHOW statement is shown in [Figure 7.5](#).

Figure 7.5 Parameter Estimates of the Count Regression Model

The CNTSELECT Procedure

Model fit results restored from item store COUNTREGMODEL:

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.910479	0.090515	10.06	<.0001
age	1	-0.626803	0.058547	-10.71	<.0001
gender	1	1.025034	0.032099	31.93	<.0001
carType	1	0.615165	0.031153	19.75	<.0001
annualMiles	1	-1.010276	0.017512	-57.69	<.0001
education	1	-0.280246	0.021677	-12.93	<.0001
_Alpha	1	0.318403	0.020090	15.85	<.0001

The following PROC SEVSELECT step fits the severity scale regression models for all the common distributions that are predefined in the procedure:

```

/* Fit severity models for the magnitude of losses */
proc sevselect data=mylib.losses outest=mylib.sevregest print=all;
    loss lossamount;
    scalemodel carType carSafety income;
    dist _predef_;
    nloptions maxiter=100;
run;

```

The comparison of fit statistics of various scale regression models is shown in Figure 7.6. The scale regression model based on the lognormal distribution is deemed the best-fitting model according to the likelihood-based statistics, whereas the scale regression model based on the Pareto distribution is deemed the best-fitting model according to the statistics based on the empirical distribution function (EDF).

Figure 7.6 Severity Model Comparison

The SEVSELECT Procedure

All Fit Statistics							
Distribution	-2 Log Likelihood	AIC	AICC	SBC	KS	AD	CvM
Burr	127231	127243	127243	127286	4.66462	75.26361	9.17877

Asterisk (*) denotes the best model in the column.

Now, you are ready to analyze the distribution of the aggregate loss that can be expected from a specific policyholder. First, you need to encode and scale the policyholder's information into the appropriate regressor variables of a data table. This table is called the scenario data table. Note that you need to follow the same encoding and scaling method for the regressor variables in the scenario data table as you use for the regressor variables in the input data tables of the SEVSELECT and CNTSELECT procedures. The following DATA steps create the scenario data table `mylib.SinglePolicy`, which contains a scenario that consists of a 59-year-old male policyholder who has an advanced degree, earns 159,870, and drives a sedan that has a very high safety rating about 11,474 miles annually:

```
/* Generate the scenario data table for single policyholder */
data singlePolicy(keep=age gender carType annualMiles
                  education carSafety income);
    age = 59/50;           * age scaled by 50;
    gender = 2;           * male;
    carType = 1;          * sedan;
    annualMiles = 11474/5000; * miles scaled by 5,000;
    education = 3;        * advanced degree;
    carSafety = 0.99532;   * car safety in the range (0,1);
    income = 159870/100000; * annual income scaled by 100,000;
    output;
run;

/* Load the data */
data mylib.singlePolicy;
    set singlePolicy;
run;
```

The following PROC CCDM step analyzes the compound distribution of the aggregate loss that the policyholder in the scenario data table `mylib.SinglePolicy` incurs in a year by using the frequency model from the item store `mylib.CountregModel` and the two best severity models, lognormal and Pareto, from the data

table mylib.SevRegEst:

```
/* Simulate the aggregate loss distribution for the scenario
   with single policyholder */
proc ccdm data=mylib.singlePolicy nreplicates=10000 seed=13579 print=all
    countstore=mylib.countregmodel severityest=mylib.sevregist;
    severitymodel logn pareto;
    outsum out=mylib.onepolicysum mean stddev skew kurtosis median
    pctlpts=97.5 to 99.5 by 1;
run;
```

The results from the preceding PROC CCDM step are shown in [Figure 7.7](#).

When you use a severity scale regression model, the “Compound Distribution Information” table displays the severity scale regression effects that PROC CCDM uses. PROC CCDM detects the severity regression effects automatically by examining the metadata that PROC SEVSELECT stores in the SEVERITYEST= data table and verifies the existence of the individual regressors in the DATA= data table.

Percentile Method = 5	

The “Sample Summary Statistics” and “Sample Percentiles” tables in [Figure 7.7](#) show estimates of the aggregate loss distribution for the lognormal severity model. The percentiles table shows that the distribution is highly skewed to the right; this is also confirmed by the skewness estimate. The median estimate of 0 can be interpreted in two ways. One way is to conclude that the policyholder will not incur any loss in 50% of the years during which he or she is insured. The other way is to conclude that 50% of policyholders who have the characteristics of this policyholder will not incur any loss in a given year. However, there is a 2.5% chance that the policyholder will incur a loss that exceeds the 97.5th percentile in any given year and a 0.5% chance that the policyholder will incur a loss that exceeds the 99.5th percentile in any given year.

If the aggregate loss sample is simulated by using the Pareto severity model, then the results are as shown in [Figure 7.8](#). These estimates are very close to the values that the lognormal severity model predicts.

The scenario that you just analyzed contains only one policyholder. You can expand the scenario to include multiple policyholders. The following DATA step simulates the data table `mylib.GroupOfPolicies`, which records information about five different policyholders, as shown in [Figure 7.9](#):

```
/* Generate the scenario data table for multiple policyholders */
data groupOfPolicies(keep=policyholderId age gender carType annualMiles
                    education carSafety income);
  call streaminit(67897);

  do policyholderId=1 to 5;
    age = MAX(int(rand('NORMAL', 35, 15)),16)/50;

    if (rand('UNIFORM') < 0.5) then gender = 1; * female;
    else gender = 2; * male;

    if (rand('UNIFORM') < 0.7) then carType = 1; * sedan;
    else carType = 2; * SUV;

    annualMiles = MAX(1000, int(rand('NORMAL', 12000, 5000)))/5000;

    educationLevel = rand('UNIFORM');
    if (educationLevel < 0.5) then education = 1; *high school graduate;
    else if (educationLevel < 0.85) then education = 2; *college graduate;
    else education = 3; *advanced degree;

    carSafety = rand('UNIFORM'); /* scaled to be between 0 & 1 */

    income = MAX(15000,int(rand('NORMAL', education*30000, 50000)))/100000;

    output;
  end;
run;

/* Load the data */
data mylib.groupOfPolicies;
```

```
set groupOfPolicies;
run;
```

Figure 7.9 Scenario Analysis Data for Multiple Policyholders

policyholderId	age	gender	carType	annualMiles	education	carSafety	income
1	1.18	2	1	2.2948	3	0.99532	1.59870
2	0.66	2	1	2.6718	2	0.86412	0.84459
3	0.64	2	2	1.9528	1	0.86478	0.50177
4	0.46	1	2	2.6402	2	0.27062	1.18870
5	0.62	1	1	1.7294	1	0.32830	0.37694

The following PROC CCDM step conducts a scenario analysis for the aggregate loss that is incurred by all five policyholders in the data table mylib.GroupOfPolicies together in one year:

```
/* Simulate the aggregate loss distribution for the scenario
   of multiple policyholders */
proc ccdm data=mylib.groupOfPolicies nreplicates=10000 seed=13579 print=all
    countstore=mylib.countregmodel severityest=mylib.sevregest
    plots=(conditionaldensity(rightq=0.95)) nperturbedSamples=50;
    severitymodel logn pareto;
    outsum out=mylib.multipolicysum mean stddev skew kurtosis median
    pctlpts=97.5 to 99.5 by 1;
run;
```

The preceding PROC CCDM step conducts perturbation analysis by simulating 50 perturbed samples. The perturbation summary results for the lognormal severity model are shown in [Figure 7.10](#), and the results for the Pareto severity model are shown in [Figure 7.11](#).

Figure 7.10 Perturbation Analysis of Losses from Multiple Policyholders with Lognormal Severity Model

The CCDM Procedure

Severity Model: Logn
Count Model: NegBin(p=2)

Compound Distribution Information	
Severity Model	Lognormal Distribution
Scale Model Effects	carSafety carType income
Count Model	NegBin(p=2) Model in Item Store COUNTREGMODEL

Sample Perturbation Analysis		
Statistic	Estimate	Standard Error
Mean	5318.6	175.49858
Standard Deviation	4179.3	141.45815
Variance	17486679	1178659.7
Skewness	2.09037	0.32112
Kurtosis	10.92294	7.21369
Number of Perturbed Samples = 50		
Size of Each Sample = 10000		

Figure 7.10 *continued*

Sample Percentile Perturbation Analysis		
Percentile	Estimate	Standard Error
1	199.34899	27.70726
5	745.77631	53.38547
25	2385.1	104.32994
50	4321.0	160.79384
75	7149.7	238.12755
95	13146.5	422.60230
95	13146.5	422.60230
97.5	15820.5	517.56323
98.5	17880.0	660.76788
99	19623.3	740.16275
99.5	22674.1	1032.8
Number of Perturbed Samples = 50		
Size of Each Sample = 10000		

If the severity of each loss follows the fitted Pareto distribution, then you can expect an average loss and a worst-case loss as shown in [Figure 7.11](#).

The numbers for lognormal and Pareto are well within one or two standard errors of each other, which indicates that the aggregate loss distribution is less sensitive to the choice of these two severity distributions in this particular example. You can use the results from either of them.

99.5	20512.6	819.42806
Number of Perturbed Samples = 50		
Size of Each Sample = 10000		

The PLOTS=CONDITIONALDENSITY option that is used in the preceding PROC CCDM step creates the conditional density plots for the body and right-tail regions of the density function of the aggregate loss. The plots for the aggregate loss sample that is generated by using the lognormal severity model are shown in Figure 7.12. The plot on the left side is the plot of $\Pr(Y|Y \leq 95\text{th percentile})$, where the limit is as specified by the RIGHTQ=0.95 suboption of the PLOTS=CONDITIONALDENSITY option. The plot on the right side is the plot of $\Pr(Y|Y > 95\text{th percentile})$, which helps you visualize the right-tail region of the density function. You can also request the plot of the left tail by specifying the LEFTQ= suboption if you want to explore the details of the left tail region. The conditional density plots are always produced by using the unperturbed sample.

Figure 7.12 Conditional Density Plots for the Aggregate Loss of Multiple Policyholders

Syntax: CCDM Procedure

Functional Summary

Table 7.1 summarizes the statements and options available in the CCDM procedure.

Table 7.1 PROC CCDM Functional Summary

Description	Statement	Option
Statements		
Specifies the names of severity distribution models	SEVERITYMODEL	
Specifies externally simulated count data	EXTERNALCOUNTS	
Specifies a count distribution that has fixed parameter values	COUNTMODEL	
Specifies simulated symbols and their probability distributions	SIMULATEDSYMBOL	
Specifies where and how the full simulated samples are written	OUTPUT	
Specifies where and how the summary statistics of simulated samples are written	OUTSUM	
Specifies the ODS tables to display (an alternative to the PRINT= option)	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	
Specifies programming statements that define an objective function	Programming statements	
Data Table Options		
Specifies the input data table	PROC CCDM	DATA=
Specifies the output data table for the individual severity draws	PROC CCDM	OUTDRAW=
Specifies the output data table for the full simulated samples	OUTPUT	OUT=
Specifies the output data table for the summary statistics	OUTSUM	OUT=
Model Input Options		
Specifies the variable that contains externally simulated counts	EXTERNALCOUNTS	COUNT=
Specifies the item store that contains the frequency (count) model	PROC CCDM	COUNTSTORE=
Specifies the replicate identifier variable for external counts	EXTERNALCOUNTS	ID=
Specifies the input data table for parameter estimates of the severity models	PROC CCDM	SEVERITYEST=
Specifies the item store for parameter estimates of the severity models	PROC CCDM	SEVERITYSTORE=

Table 7.1 *continued*

Description	Statement	Option
Simulation Options		
Specifies the adjusted severity symbols in the programming statements	PROC CCDM	ADJUSTEDSEVERITY=
Specifies that the covariance estimates be ignored for perturbation analysis	PROC CCDM	IGNORECOV
Specifies the left-truncation threshold for truncating a severity distribution	PROC CCDM	LEFTTRUNCATION=
Specifies the upper limit on the count for each sample point	PROC CCDM	MAXCOUNTDRAW=
Specifies the number of parameter-perturbed samples to be simulated	PROC CCDM	NPERTURBEDSAMPLES=
Specifies a number that controls the size of the simulated sample	PROC CCDM	NREPLICATES=
Specifies how the perturbed samples are generated	PROC CCDM	PERTURBMODE=
Specifies the right-truncation limit for truncating a severity distribution	PROC CCDM	RIGHTTRUNCATION=
Specifies a seed for the internal pseudorandom number generator	PROC CCDM	SEED=
Specifies the type of aggregate loss you want to simulate	PROC CCDM	SIMULATIONMODE=
Output Preparation Options		
Specifies the variables for the aggregate adjusted loss samples	OUTPUT	ADJSAMPLEVAR=
Specifies that a backward compatible output style be used for the case of a single adjusted severity symbol	PROC CCDM	ONEADJSEVCOMPAT
Specifies the names of the variables for percentiles	OUTSUM	PCTLNAME=
Specifies the decimal precision to form default percentile variable names	OUTSUM	PCTLNDEC=
Specifies percentiles to compute and report	OUTSUM	PCTLPTS=
Specifies the method to compute the percentiles	PROC CCDM	PCTLDEF=
Specifies that all perturbed samples be written to the OUT= data table	OUTPUT	PERTURBOUT
Specifies the variable for the aggregate loss sample	OUTPUT	SAMPLEVAR=
Specifies that zero-valued aggregate losses be removed from the aggregate loss sample	PROC CCDM	TRUNCATEZEROS
Specifies the denominator for computing second- and higher-order moments	PROC CCDM	VARDEF=
Displayed Output Options		
Suppresses all displayed output	PROC CCDM	NOPRINT

Table 7.1 *continued*

Description	Statement	Option
Specifies which graphical output to create	PROC CCDM	PLOTS=
Specifies which displayed output to produce	PROC CCDM	PRINT=

PROC CCDM Statement

PROC CCDM *options* ;

The PROC CCDM statement invokes the procedure. You can specify the following *options*, which are listed in alphabetical order.

ADJUSTEDSEVERITY=*symbol-name*

ADJSEV=*symbol-name*

ADJUSTEDSEVERITY=(*symbol-name* <... *symbol-name* >)

ADJSEV=(*symbol-name* <... *symbol-name* >)

names one or more symbols that represent an adjusted severity value in the SAS programming statements that you specify. If you specify more than one *symbol-name*, then separate them with spaces and enclose them in parentheses. Each *symbol-name* is a SAS name that conforms to the naming conventions of a SAS variable. For more information, see the section “[Programming Statements](#)” on page 216.

COUNTSTORE=*libref.data-table*

names the input data table that contains all the information about the frequency (count) model in the form of an item store. The CNTSELECT procedure generates this item store data table when you use the STORE= option.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 174. The *libref* must be identical to the *libref* that you specify in the DATA= option.

The exogenous variables in the frequency model, if any, are deduced from this item store. The DATA= data table must contain all those variables.

If you specify a BY statement in the PROC CNTSELECT step that creates the COUNTSTORE= item store, then you must specify an identical BY statement in the PROC CCDM step.

You must specify this option if you do not specify the COUNTMODEL or EXTERNALCOUNTS statement. This option is ignored if you specify the EXTERNALCOUNTS statement, because PROC CCDM does not need to simulate frequency counts internally when you specify externally simulated counts.

DATA=libref.data-table

names the input data table for PROC CCDM to use. *libref.data-table* is a two-level name, where

<i>libref</i>	refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about <i>libref</i> , see the section “Using CAS Sessions and CAS Engine Librefs” on page 174.
<i>data-table</i>	specifies the name of the input data table.

The DATA= data table specifies information about the scenario for which you want to estimate the aggregate loss distribution. It is expected to contain the values of regression variables in the frequency or severity model and severity adjustment variables that you use in the programming statements.

IGNORECOV**IGNOREPARMCOVARIANCE**

specifies that the covariance estimates be ignored for perturbation analysis. If you specify this option, then even if the covariance estimates of severity or frequency model parameters are valid, they are not used for perturbation analysis, and only standard errors are used. This enables you to force independence among parameters. However, perturbation analysis based on covariance estimates is more accurate than perturbation analysis based on the standard errors alone.

For more information about parameter perturbation analysis, see the section [“Parameter Perturbation Analysis”](#) on page 239.

LEFTTRUNCATION=number**LTRUNC=number**

specifies the left-truncation threshold for truncating a severity distribution.

Specifying this option, and optionally the **RIGHTTRUNCATION=** option, enables you to simulate from a truncated severity distribution. For more information, see the section [“Making a Random Draw from a Truncated Severity Distribution”](#) on page 225.

MAXCOUNTDRAW=number**MAXCOUNT=number**

specifies an upper limit on the number of loss events (count) that is used for simulating one aggregate loss sample point. If *number* is equal to $N_{\max}$, then any count greater than $N_{\max}$ is assumed to be equal to $N_{\max}$, and only $N_{\max}$ severity draws are made to compute one point in the aggregate loss sample.

If you specify this option and also specify the COUNTSTORE= item store or the COUNTMODEL statement, then the limit is applied to each count that PROC CCDM randomly draws from the count distribution. Any count draw larger than *number* is replaced by *number*.

If you specify this option and also specify the EXTERNALCOUNTS statement, then the limit is applied to each observation in the DATA= data table, and any value of the COUNT= variable larger than *number* is replaced by *number*.

If you do not specify this option, then a default value of 1,000 is used.

If you specify a *number* significantly larger than 1,000, then PROC CCDM might take a very long time to complete the simulation, especially when some counts are closer to the limit.

NOPRINT

turns off all displayed output. If you specify this option, then PROC CCDM ignores any value that you specify for the PRINT= option.

NPERTURBEDSAMPLES=number**NPERTURB=number**

performs parameter perturbation analysis, where *number* determines how many perturbed parameter sets are generated. A separate full sample is simulated for each set of perturbed parameter values. The summary statistics and percentiles are computed for each such perturbed sample, and their values are aggregated across the samples to compute the mean and standard deviation of each summary statistic and percentile.

The parameter perturbation analysis makes random draws of parameter values from a multivariate normal distribution if the covariance estimates of the parameters are available. For the multivariate normal distribution of severity model parameters, PROC CCDM attempts to read the covariance estimates from the SEVERITYEST= data table or the SEVERITYSTORE= item store. For the multivariate normal distribution of count model parameters, PROC CCDM attempts to read the covariance estimates from the item store that is specified in the COUNTSTORE= option. If covariance estimates are not available or valid, or if you specify the IGNORECOV option, then for each parameter, PROC CCDM makes a random draw from the univariate normal distribution whose mean and standard deviation are equal to that parameter's point estimate and standard error, respectively. The standard errors for severity model parameters are read from either the SEVERITYEST= data table or the SEVERITYSTORE= item store. The standard errors for count model parameters are either read from the COUNTSTORE= item store or you must specify them in the COUNTMODEL statement. If neither covariance nor standard error estimates are available for any severity or frequency model parameter, then perturbation analysis is not conducted.

If you specify the PRINT=ALL or PRINT=PERTURBSUMMARY option, then a summary of the perturbation analysis is printed for the core summary statistics and the percentiles of the aggregate loss distribution. If you specify the OUTSUM statement, then the requested summary statistics are written to the OUTSUM= data table for each perturbed sample. You can also optionally request that each perturbed sample be written in its entirety to the OUT= data table by specifying the PERTURBOUT option in the OUTPUT statement.

For more information about parameter perturbation analysis, see the section “[Parameter Perturbation Analysis](#)” on page 239.

NREPLICATES=number**NREP=number**

specifies a *number* that controls the size of the compound distribution sample that PROC CCDM simulates. The *number* is interpreted differently based on whether you specify the EXTERNALCOUNTS statement.

If you do not specify the EXTERNALCOUNTS statement, then the sample size is equal to *number*. If you do not specify this option, then a default value of 100,000 is used.

If you specify the EXTERNALCOUNTS statement, then the number of replicates that you specify in the DATA= data table is multiplied by *number* to get the total size of the compound distribution sample. If you do not specify this option, then a default value of 1 is used.

ONEADJSEVCOMPAT

specifies that the output of the case of single adjusted severity symbol be prepared by using the same method as used by the versions of the CCDM procedure prior to SAS Econometrics 8.5. In particular, specifying this option causes the following output-related changes, where *sym* denotes the name of the single adjusted severity symbol that you specify in the [ADJUSTEDSEVERITY=](#) option:

- If you specify the OUTPUT statement, then the default name of the adjusted severity variable in the OUTSAMPLE= table is `_AGGADJSEV_` instead of *sym*.
- If you specify the OUTSUM statement, then the default value in the `_SAMPLEVAR_` column of the OUTSUM= table is `_AGGADJSEV_` instead of *sym* for the rows that correspond to the aggregate adjusted severity.
- The ODS path for the adjusted severity group's output table or plot uses `AggregateAdjustedLoss` instead of *sym*.
- The label for the adjusted severity group in the table of contents of a SAS client is "Aggregate Adjusted Loss" instead of "Aggregate Adjusted Loss *sym*."
- The title of the SummaryStatistics ODS table is "Adjusted Sample Summary Statistics" instead of "Summary Statistics for *sym*."
- The title of the PerturbedSummary ODS table is "Adjusted Sample Perturbation Analysis" instead of "Sample Perturbation Analysis for *sym*."
- The title of the Percentiles ODS table is "Adjusted Sample Percentiles" instead of "Percentiles for *sym*."
- The title of the PerturbedPctlSummary ODS table is "Adjusted Sample Percentile Perturbation Analysis" instead of "Percentile Perturbation Analysis for *sym*."
- The titles of plots use just "Adjusted Sample" instead of "Adjusted Sample *sym*."
- The X-axis variable label in plots is just "Aggregate Adjusted Loss" instead of "Aggregate Adjusted Loss *sym*."

When you do not specify this option, the style of the output for the case of a single adjusted severity symbol is no different from the style of the output for the case of more than one adjusted severity symbol.

OUTDRAW=*libref.data-table*

specifies the output data table to contain the individual severity random draws. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section "Using CAS Sessions and CAS Engine Librefs" on page 174. The *libref* must be identical to the *libref* that you specify in the [DATA=](#) option.

For more information about the variables in the OUTDRAW= data table, see the section "[OUTDRAW= Data Table](#)" on page 247.

PCTLDEF=*percentile-method*

specifies the method of computing the percentiles of the compound distribution. The *percentile-method* can be 1, 2, 3, 4, or 5. By default, PCTLDEF=5. For more information, see the description of the PCTLDEF= option in the UNIVARIATE procedure in the [Base SAS Procedures Guide: Statistical Procedures](#).

PERTURBMODE=*mode*

PERTURBMETHOD=*mode*

specifies the method to use for generating perturbed samples.

This option has no effect if you do not specify the **NPERTURBEDSAMPLES=** option or if you specify the **EXTERNALCOUNTS** statement.

Let P and W denote the values of the **NPERTURBEDSAMPLES=** option and the number of worker nodes in the CAS session that the procedure is running in, respectively. Also, let N denote the value of the **NREPLICATES=** option.

You can specify one of the following *modes*:

AUTO | SYNC | 1

generates perturbed samples in either a distributed or partitioned manner, depending on the values of P and W , as follows:

- If $P < W$, then each perturbed sample is distributed across all W workers, such that each worker generates a subsample of approximately N/W points of each perturbed aggregate loss sample. If you specify the **PERTURBOUT** option in the **OUTPUT** statement, then observations that have the same **_DRAWID_** variable value are distributed across all worker nodes. The controller node needs to gather the subsamples from all the worker nodes in order to compute the percentiles, and perturbed samples are generated sequentially for each severity model within each BY group.
- If $P \geq W$, then perturbed samples are generated in a partitioned manner such that each worker node generates approximately P/W perturbed samples, each of size N . If you specify the **PERTURBOUT** option in the **OUTPUT** statement, then observations that have the same **_DRAWID_** variable value are available on only one of the worker nodes. There is no need to communicate any sample data to the controller node, because each worker node has enough data to compute the percentiles of each perturbed sample. The controller node gathers only the summary statistics and percentiles of perturbed samples from all worker nodes. Further, each worker node can simulate its assigned P/W perturbed samples independently of other worker nodes. Together, these two aspects make the perturbation analysis more efficient.

DIST | SYNCDIST | 2

always generates perturbed samples in a distributed manner, irrespective of the values of P and W . This option's behavior is equivalent to the behavior of the **AUTO** option in the $P < W$ case.

It is recommended that you specify the **AUTO mode**. By default, **PERTURBMETHOD=DIST** to ensure that the current release of PROC CCDM produces, by default, the same perturbation results as releases prior to SAS Econometrics 8.4.

PLOTS <(global-plot-options)> =*plot-request-option*

PLOTS <(global-plot-options)> =(*plot-request-option* . . . *plot-request-option*)

specifies the desired graphical output.

By default, the CCDM procedure produces no graphical output.

When you request plots by using this option, PROC CCDM creates a plot data table on the server. This table contains an estimate of the empirical distribution function (EDF) for a carefully selected subsample of the simulated aggregate loss sample. PROC CCDM brings the plot data table back to the client machine where your SAS session is running and uses it to create all the plots that you specify.

You can specify the following *global-plot-options*:

ONLY

turns off the default graphical output and creates only the requested plots.

NOBS=number

specifies the approximate number of observations in the plot data table. The larger the *number*, the more accurate are the plots, but also the larger the size of the data that need to be brought back to the client machine. A larger plot data table not only requires more time and resources to prepare but can also cost you additional money if the data movement on the client-server connection is metered.

If you specify a nonzero *number*, then it must be greater than 10. If you do not specify this option or if you specify NOBS=0, then a default value of 5,000 is used.

NADJSEVTOPLOT=k

NADJSEV=k

specifies the number of aggregate adjusted loss samples for which to create the requested plots. PROC CCDM creates plots for the first *k* adjusted severity symbols that you specify in the [ADJUSTEDSEVERITY=](#) option.

This option is ignored if you do not specify the [ADJUSTEDSEVERITY=](#) option and the programming statements to adjust the simulated severity values.

If you specify *m* symbols in the [ADJUSTEDSEVERITY=](#) option and if $k > m$, then PROC CCDM creates the requested plots for all adjusted severity symbols.

Note that PROC CCDM prepares a separate plot data table for each of the *k* aggregate adjusted loss samples, so the amount of data that PROC CCDM needs to bring back to the client machine increases linearly with the value of *k*.

By default, PROC CCDM does not create plots for aggregate adjusted loss samples—that is, NADJSEVTOPLOT=0 by default.

You control which plots to create for each aggregate loss sample by specifying the *plot-request-options*. If you specify more than one *plot-request-option*, then separate them with spaces and enclose them in parentheses. You can specify the following *plot-request-options*:

ALL

displays all the graphical output.

CONDITIONALDENSITY (*conditional-density-plot-options*)

CONDPDF (*conditional-density-plot-options*)

creates a group of plots of the conditional density functions estimates. The group contains at most three plots, each conditional on the value of the aggregate loss being in one of the three regions that are defined by the quantiles that you specify in the following *conditional-density-plot-options*:

LEFTQ=number

specifies the quantile in the range (0,1) that marks the end of the left-tail region. If you specify a value of l for *number*, then the left-tail region is defined as the set of values that are less than or equal to q_l , where q_l is the l th quantile. For the left-tail region, nonparametric estimates of the conditional probability density function $f_S^l(s) = \Pr[S = s | S \leq q_l]$ are plotted. The value of q_l is estimated by the 100/ l th percentile of the simulated compound distribution sample.

If you do not specify this option or you specify a missing value for this option, then the left-tail region is not plotted.

RIGHTQ=number

specifies the quantile in the range (0,1) that marks the beginning of the right-tail region. If you specify a value of r for *number*, then the right-tail region is defined as the set of values that are greater than q_r , where q_r is the r th quantile. For the right-tail region, nonparametric estimates of the conditional probability density function $f_S^r(s) = \Pr[S = s | S > q_r]$ are plotted. The value of q_r is estimated by the 100/ r th percentile of the simulated compound distribution sample.

If you do not specify this option or you specify a missing value for this option, then the right-tail region is not plotted.

You must specify a nonmissing value for at least one of the preceding two options. For the region between the LEFTQ= and RIGHTQ= quantiles, which is referred to as the central or body region, nonparametric estimates of the conditional probability density function $f_S^c(s) = \Pr[S = s | q_l < S \leq q_r]$ are plotted. If you do not specify a LEFTQ= value, then q_l is assumed to be 0. If you do not specify a RIGHTQ= value, then q_r is assumed to be ∞ .

DENSITY

creates a plot of the nonparametric estimates of the probability density function (in particular, histogram and kernel density estimates) of the compound distribution.

EDF <(edf-plot-option)>

creates a plot of the nonparametric estimates of the cumulative distribution function of the compound distribution.

You can request that the confidence interval be plotted by specifying the following *edf-plot-option*:

ALPHA=number

specifies the confidence level in the (0,1) range that is used for computing the confidence intervals for the EDF estimates. If you specify a value of α for *number*, then the upper and lower confidence limits for the confidence level of $100(1 - \alpha)$ are plotted.

NONE

displays none of the graphical output. If you specify this option, then it overrides all other plot request options. The default graphical output is also suppressed.

PRINT <(*global-display-option*)> =*display-option*

PRINT <(*global-display-option*)> =(display-option ... display-option)

specifies the desired displayed output. If you specify more than one *display-option*, then separate them with spaces and enclose them in parentheses.

You can specify the following *global-display-option*:

ONLY

turns off the default displayed output and displays only the requested output.

You can specify the following *display-options*:

ALL

displays all the output.

NONE

displays no output. If you specify this option, then it overrides all other display options. The default displayed output is also suppressed.

PERCENTILES

displays the percentiles of the compound distribution sample. This includes all the predefined percentiles and percentiles that you request in the OUTSUM statement.

PERTURBSUMMARY

displays the mean and standard deviation of the summary statistics and percentiles that are taken across all *P* samples that the procedure produces by perturbing the model parameters, where *P* is the value of the NPERTURBEDSAMPLES= option that you specify in the PROC CCDM statement.

SUMMARYSTATISTICS | SUMSTAT

displays the summary statistics of the compound distribution sample.

If you do not specify the PRINT= option or the ONLY *global-display-option*, then the procedure behaves as if you have specified PRINT=(SUMMARYSTATISTICS).

RIGHTTRUNCATION=*number*

RTRUNC=*number*

specifies the right-truncation limit for truncating a severity distribution.

Specifying this option, and optionally the [LEFTTRUNCATION](#)= option, enables you to simulate from a truncated severity distribution. For more information, see the section “[Making a Random Draw from a Truncated Severity Distribution](#)” on page 225.

SEED=*number*

specifies the integer to use as the seed in generating the pseudorandom numbers that are used for simulating severity and frequency values.

If you do not specify the seed, or if *number* is negative or 0, then PROC CCDM uses the time of day from the computer’s clock as the seed.

SEVERITYEST=libref.data-table

names the input data table that contains the parameter estimates for the severity models. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 174. The *libref* must be identical to the *libref* that you specify in the [DATA=](#) option. This data table must be an [OUTEST=](#) data table that the [SEVSELECT](#) procedure produces.

The names of the regression variables in the scale regression models, if any, are deduced from this data table. If the severity models are scale regression models, then the [DATA=](#) data table must contain all the regressors in the scale regression models.

To ensure that PROC CCDM correctly matches the values of regressors and the values of regression parameter estimates, you need to ensure that names of the regressors in the [DATA=](#) data table match the names of the regressors that you specify in the [SCALEMODEL](#) statement of the PROC [SEVSELECT](#) step that fits the severity models.

If you specify a [BY](#) statement in the PROC [SEVSELECT](#) step that creates the [SEVERITYEST=](#) data table, then you must specify an identical [BY](#) statement in the PROC CCDM step.

SEVERITYSTORE=libref.data-table**SEVSTORE=libref.data-table**

specifies the input data table that contains the context and estimates of the severity models in the form of an item store. Specifying the [OUTSTORE=](#) option in a PROC [SEVSELECT](#) step creates this item store data table.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 174. The *libref* must be identical to the *libref* that you specify in the [DATA=](#) option.

If your severity models contain classification or interaction effects, then you need to use this option instead of the [SEVERITYEST=](#) option to specify the estimates of the severity models. If you specify this option, you cannot specify the [SEVERITYEST=](#) option.

If you specify a [BY](#) statement in the PROC [SEVSELECT](#) step that creates the [SEVERITYSTORE=](#) item store, then you must specify an identical [BY](#) statement in the PROC CCDM step.

SIMULATIONMODE=mode

specifies the mode of simulating aggregate loss. You can specify one of the following *modes*:

COLLECTIVERISK**CR**

specifies the collective risk mode. Aggregate loss is defined as $S = \sum_{i=1}^N X_i$, where X_i denotes a continuous random variable that represents the severity of one loss event and N denotes the discrete random variable that represents the number of loss events you expect to see in a particular time period. The severity random variables $\{X_i\}$ that are associated with all loss events are assumed to be iid. For each random frequency draw N , PROC CCDM makes N random draws from the severity distribution and adds those severity draws to compute one sample point in the aggregate loss sample.

If you specify this mode (or choose it by default) and if you specify the frequency distribution by using the [COUNTMODEL](#) statement, then the count distribution must be a discrete distribution.

CUSTOM**CSTM**

specifies the custom mode. In this mode, you use programming statements to combine the severity and frequency values according to your business logic in order to compute the aggregate loss. If you specify this mode, then you must also use the `ADJUSTEDSEVERITY=` option to specify an aggregate loss symbol that your programming statements compute. For each random frequency draw N , PROC CCDM makes one random draw, X , from the severity distribution and sets the keyword symbols `_FREQ_` and `_SEV_` to N and X , respectively. It then executes your programming statements to compute one sample point in the aggregate loss sample.

This mode is especially useful if you also use the `SIMULATEDSYMBOL` statement to specify some stochastic variables that you have externally estimated to follow certain parametric probability distributions. For example, the following statements simulate a sample of the total paid loss `paidLoss` as $P = NEX + C$, where N denotes the average frequency of loss events per exposure and follows a lognormal distribution with $\mu = 3$ and $\sigma = 0.5$, E denotes the estimate of the total exposure in a particular time period and follows a normal distribution $\mathcal{N}(1000, 75)$, X denotes the average severity of a loss event, and C denotes the random change in losses from one time period to next and follows a normal distribution $\mathcal{N}(500, 10)$:

```
proc ccdm severitystore=mylib.sevstore simulationmode=custom
    adjustedseverity=paidLoss;
    countmodel lognormal(3,0.5);
    simulatedsymbol E ~ normal(1000, 75) C ~ normal(500, 10);
    paidLoss = _freq_ * E * _sev_ + C;
run;
```

PUREPREMIUM**PP**

specifies the pure premium mode. Aggregate loss is defined as $S = NX$, where N denotes the average frequency of loss events you expect to see in a particular time period and X denotes a continuous random variable that represents the average severity of the loss events in that time period. For each random frequency draw N , PROC CCDM makes one random draw, X , from the severity distribution and multiplies N and X to compute one sample point in the aggregate loss sample.

By default, `SIMULATIONMODE=COLLECTIVERISK`.

TRUNCATEZEROS

truncates (removes) zero-valued aggregate loss values from the aggregate loss sample.

The value of the aggregate loss is 0 when the sum of randomly drawn counts for all observations is 0 for the internally simulated counts or when the total count for a replication is 0 in the external counts data table.

If you omit this option, then PROC CCDM keeps the zero-valued aggregate losses in the output sample.

VARDEF=divisor

specifies the divisor to use in the calculation of variance, standard deviation, kurtosis, and skewness of the compound distribution sample. If the sample size is N , then you can specify one of the following values for the *divisor*:

DF

sets the divisor for variance to $N - 1$. This also changes the definitions of skewness and kurtosis.

N

sets the divisor to N .

By default, VARDEF=DF. For more information, see the section “Descriptive Statistics” on page 244.

BY Statement

BY *variable-list* ;

You can use the BY statement in the CCDM procedure to process the input data table in groups of observations defined by the BY variables.

If you specify the BY statement, then unlike procedures that do not use a CAS server, PROC CCDM does not need the input data table to be sorted in the order of the BY variables. As a consequence, the NOTSORTED and DESCENDING options have no effect, and PROC CCDM ignores them.

COUNTMODEL Statement

COUNTMODEL *distribution-name*(*parameter-value* < (*value-option*)>< , > ... *parameter-value* < (*value-option*)>) ;

The COUNTMODEL statement enables you to specify a parametric count model that has fixed parameter values. You must specify this statement if you do not specify the COUNTSTORE= option or the EXTERNALCOUNTS statement. On the other hand, PROC CCDM ignores this statement if you specify either the COUNTSTORE= option or the EXTERNALCOUNTS statement.

You must specify the following:

distribution-name

identifies your desired distribution. For a list of supported distributions and their acceptable names, see Table 7.2 or Table 7.3 in the section “Fixed Parameter-Value Distributions” on page 240. Each distribution accepts a fixed number of parameters in a specific order.

parameter-values

specifies the values of the distribution parameters. You must specify as many *parameter-values* as the expected number of parameters for the distribution that corresponds to *distribution-name*. PROC CCDM associates your specified values to parameters in the order the parameters are listed from top to bottom in the Parameters column of Table 7.2 or Table 7.3. The Parameters column also specifies the acceptable bounds, if any, for each parameter. Your specified *parameter-value* must be within those bounds.

You can optionally specify a standard error for each parameter by enclosing the following *value-option* in parentheses immediately after a parameter's value:

STDERROR=*number*

SE=*number*

number

specifies the standard error of the parameter. If you specify a value v and standard error s for a parameter, then PROC CCDDM assumes that the parameter follows a normal distribution $\mathcal{N}(v, s)$.

You can separate the parameter value specifications by using either a comma or a space.

The following example COUNTMODEL statement specifies that the counts follow the standard negative binomial distribution with parameters $p = 0.7$ and $n = 5$:

```
countmodel negbin(0.7 5);
```

If you request perturbation analysis by specifying a positive value for the **NPURTURBEDSAMPLES=** option and the parameters of your count distribution are stochastic, then it is recommended that you specify the standard error for each parameter. The following COUNTMODEL statement specifies that the counts follow the Weibull distribution with parameters $\theta = 50$ and $\tau = 0.75$ such that the standard errors for the θ and τ parameters are 3.5 and 0.25, respectively:

```
countmodel weibull(50(se=3.5), 0.75(0.25));
```

With this specification, when PROC CCDDM conducts the perturbation analysis, it sets the perturbed values of θ and τ to randomly drawn quantiles from the normal distributions $\mathcal{N}(50, 3.5)$ and $\mathcal{N}(0.75, 0.25)$, respectively.

PROC CCDDM permits a continuous count distribution (such as the Weibull distribution in the preceding example) only if you use the **SIMULATIONMODE=** option to specify a simulation mode other than the collective risk mode. For example, in the pure premium simulation mode (**SIMULATIONMODE=PP**), the count might represent an average claim frequency that an insurance company observes for a type of policy in a particular time period. Such an average frequency can have fractional values that are best modeled by a continuous distribution.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[Displayed Output](#)” on page 250. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* </ options> ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

<i>key=value</i>	specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name.
<i>key</i>	specifies <i>key</i> as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[Displayed Output](#)” on page 250. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

EXTERNALCOUNTS Statement

EXTERNALCOUNTS **COUNT**=*frequency-variable* <**ID**=*replication-id-variable*> ;

The EXTERNALCOUNTS statement enables you to specify externally simulated frequency counts. By default, PROC CCDM internally simulates the number of loss events by using the frequency model from the COUNTSTORE= item store or the COUNTMODEL statement. However, if you specify the EXTERNALCOUNTS statement, then PROC CCDM uses the counts that you specify in the DATA= data table and simulates only the severity values internally.

If you specify more than one EXTERNALCOUNTS statement, only the first one is used.

You must specify the following option in the EXTERNALCOUNTS statement:

COUNT=*count-variable*

specifies the variable that contains the simulated counts. This variable must be present in the DATA= data table.

You can also specify the following option in the EXTERNALCOUNTS statement:

ID=*replication-id-variable*

specifies the variable that contains the replicate identifier. This variable must be present in the DATA= data table.

When you specify this option, you must partition the observations of the DATA= data table by the BY variables, if any, and the ID= variable. One way to partition the table is to run the following DATA step when you upload a local SAS data set to a CAS table on the CAS server, where *BY-variable-list* is the list of BY variables that is identical to the list in the BY statement:

```
data mylib.counts (partition=(<BY-variable-list> <replication-id-variable>));
  set inlib.counts;
run;
```

If the DATA= data table is already loaded onto the CAS server and not partitioned by the required set of variables, then one way to partition the table is to use PROC CAS to run the **partition** action.

If you do not specify the BY statement, then the DATA= data table must be partitioned by just the ID= variable.

If you do not specify the ID= option, then PROC CCDM assumes that each observation represents one replication. In other words, the observation number serves as the default replication identifier.

The simulation process of using the external counts to generate the compound distribution sample is described in the section “[Simulation with External Counts](#)” on page 221.

OUTPUT Statement

OUTPUT OUT=*libref.data-table* < *variable-name-option* > < / *out-option* > ;

The OUTPUT statement enables you to specify the data table to output the generated compound distribution sample.

If you specify more than one OUTPUT statement, only the first one is used.

You must specify the output data table by using the following option:

OUT=*libref.data-table*

OUTSAMPLE=*libref.data-table*

specifies the output data table to contain the simulated compound distribution sample. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the **DATA=** option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 174. The *libref* must be identical to the *libref* that you specify in the DATA= option. If you specify programming statements to adjust individual severity values, then this data table contains both unadjusted and adjusted samples.

You can specify the following *variable-name-options* to control the names of the variables that are created in the OUT= data table:

ADJSAMPLEVAR=*variable-name*

ADJSAMPLEVAR=(*variable-name* < ... *variable-name* >)

specifies the names of the variables to contain the adjusted compound distribution sample in the OUT= data table. If you specify more than one *variable-name*, then separate them with spaces and enclose them in parentheses.

This option is ignored if you do not specify the **ADJUSTEDSEVERITY=** option and the programming statements to adjust the simulated severity values.

If you specify *k* names in the ADJSAMPLEVAR= option and if you specify *m* symbols in the ADJUSTEDSEVERITY= option such that $m > k$, then the *k* names are used for the first *k* symbols. The variable names for the remaining $m - k$ symbols are the same as the corresponding symbol names. If $m < k$, then the extra $k - m$ names are ignored.

If you do not specify the ADJSAMPLEVAR= option, if you specify only one adjusted severity symbol in the ADJUSTEDSEVERITY= option, and if you specify the **ONEADJSEVCOMPAT** option, then “_AGGADJSEV_” is used by default.

SAMPLEVAR=*variable-name*

specifies the name of the variable to contain the simulated sample in the OUT= data table. If you do not specify this option, then “_AGGSEV_” is used by default.

Further, you can request that the perturbed samples be written to the OUT= data table by specifying the following *out-option*:

PERTURBOUT

writes all the perturbed samples to the OUT= data table. Each perturbed sample is identified by the value of the _DRAWID_ variable in the OUT= data table. A value of 0 indicates an unperturbed sample.

Separate compound distribution samples are generated for each combination of specified severity and frequency models. The _SEVERITYMODEL_ and _COUNTMODEL_ columns in the OUT= data table identify the severity and frequency models, respectively, that are used to generate the sample in the SAMPLEVAR= variable and ADJSAMPLEVAR= variables.

For more information about the variables in the OUTSAMPLE= data table, see the section “[OUTSAMPLE= Data Table](#)” on page 248.

OUTSUM Statement

OUTSUM **OUT=***libref.data-table* *statistic-keyword*<=*variable-name*> <... *statistic-keyword*<=*variable-name*>> <*outsum-options*> ;

The OUTSUM statement enables you to specify the data table in which PROC CCDM writes the summary statistics of the compound distribution samples.

If you specify more than one OUTSUM statement, only the first one is used.

You must specify the output data table by using the following option:

OUT=*libref.data-table*

OUTSUM=*libref.data-table*

specifies the output data table that contains the summary statistics of each of the simulated compound distribution samples. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 174. The *libref* must be identical to the *libref* that you specify in the DATA= option.

You can control the summary statistics that appear in this data table by specifying different *statistic-keywords* and *outsum-options*.

You can request that one or more predefined statistics of the compound distribution sample be written to the OUTSUM= data table. For each specification of the form *statistic-keyword*<=*variable-name*>, the statistic that is specified by the *statistic-keyword* is written to a variable named *variable-name*. If you do not specify the *variable-name*, then the statistic is written to a variable named *statistic-keyword*. You can specify the following *statistic-keywords*:

KURTOSIS

KURT

specifies the kurtosis of the compound distribution sample.

MEAN

specifies the mean of the compound distribution sample.

P01

specifies the 1st percentile of the compound distribution sample.

P05

specifies the 5th percentile of the compound distribution sample.

P10

specifies the 10th percentile of the compound distribution sample.

P25

Q1

specifies the lower or 1st quartile (the 25th percentile) of the compound distribution sample.

P50

MEDIAN

Q2

specifies the median (the 50th percentile) of the compound distribution sample.

P75

Q3

specifies the upper or 3rd quartile (the 75th percentile) of the compound distribution sample.

P90

specifies the 90th percentile of the compound distribution sample.

P95

specifies the 95th percentile of the compound distribution sample.

P99

specifies the 99th percentile of the compound distribution sample.

P99_5

P995

specifies the 99.5th percentile of the compound distribution sample.

QRANGE

specifies the interquartile range ($Q3-Q1$) of the compound distribution sample.

SKEWNESS

SKEW

specifies the skewness of the compound distribution sample.

STDDEV**STD**

specifies the standard deviation of the compound distribution sample.

All percentiles are computed by using the method that you specify in the **PCTLDEF=** option in the PROC CCDF statement. You can also request additional percentiles to be reported in the OUTSUM= data table by specifying the following *outsum-options*:

PCTLPTS=percentile-list

specifies one or more percentiles that you want to be computed and written to the OUTSUM= data table. This option is useful if you need to request percentiles that are not available in the preceding list of *statistic-keyword* values. Each percentile value must belong to the (0,100) open interval. The *percentile-list* is a comma-separated list of numbers. You can also use a list notation of the form “< number1 > to < number2 > by < increment >”. For example, the following two options are equivalent:

```
pctlpts=10, 20, 99.6, 99.7, 99.8, 99.9
pctlpts=10, 20, 99.6 to 99.9 by 0.1
```

You can specify the name of the variable for a particular percentile value in the PCTLNAME= option.

PCTLNAME=percentile-variable-name-list

specifies the names of the variables that contain the estimates of the percentiles that you request by using the PCTLPTS= option.

If you specify the PCTLNAME= option, you must specify it as the last option in the OUTSUM statement.

If you do not specify the PCTLNAME= option, then each percentile value t in the list of values in the PCTLPTS= option is written to the variable named “Pt,” where the decimal point in t , if any, is replaced by an underscore.

The *percentile-variable-name-list* is a space-separated list of names. You can also use a shortcut notation of <prefix> m –<prefix> n for two integers m and n ($m < n$) to generate the following list of names: <prefix> m , <prefix> $m + 1$, ..., and <prefix> n . For example, the following two options are equivalent:

```
pctlname=p1 p2 pc5 pc6 pc7 pc8 pc9 pc10
pctlname=p1 p2 pc5-pc10
```

The name in j th position of the expanded name list of the PCTLNAME= option is used to create a variable for a percentile value in the j th position of the expanded value list of the PCTLPTS= option. If you specify k_n names in the PCTLNAME= option and k_v percentile values in the PCTLPTS= option, and if $k_n < k_v$, then the first k_n percentiles are written to the variables that you specify. The remaining $k_v - k_n$ percentiles are written to the variables that have the name of the form P_t , where t is the text representation of the percentile value that is formed by retaining at most PCTLNDEC= digits after the decimal point and replacing the decimal point with an underscore (‘_’). For example, assume that you specify the following options:

```
pctlpts=10, 20, 99.3 to 99.5 by 0.1, 99.995
pctlname=pten ptwenty ninenine3-ninenine5
```

Then PROC CCDDM writes the 10th and 20th percentiles to the variables `pten` and `ptwenty`, respectively; the 99.3rd through 99.5th percentiles to the variables `ninenine3`, `ninenine4`, and `ninenine5`, respectively; and the remaining 99.995th percentile to the variable `P99_995`.

If a percentile value in the `PCTLPTS=` option matches a percentile value that is implied by one of the predefined percentile statistics and you specify the corresponding *statistic-keyword*, then the variable name that is implied by the *statistic-keyword*≤*variable-name* specification takes precedence over the name that you specify in the `PCTLNAME=` option. For example, assume that you specify the predefined percentile statistic of `P95`, as in the following `OUTSUM` statement:

```
outsum out=mypctls p95=ninetyfifth
      pctlpts=95 to 99 by 1 pctlname=pct95-pct99;
```

Then the 95th percentile is written to the variable `ninetyfifth` instead of the variable `pct95` that the `PCTLNAME=` option implies.

PCTLNDEC=integer-value

specifies the maximum number of decimal places to use while creating the names of the variables for the percentile values in the `PCTLPTS=` option. By default, `PCTLNDEC=3`. For example, for a percentile value of 99.9995, PROC CCDDM creates a variable named `P99_999` by default, but if you specify `PCTLNDEC=4`, then the variable is named `P99_9995`.

The `PCTLNDEC=` option is used only for percentile values for which you do not specify a name in the `PCTLNAME=` option.

Note that all variable names in the `OUTSUM=` data table have a limit of 32 characters. If a name exceeds that limit, then it is truncated to the first 32 characters. For more information about the variables in the `OUTSUM=` data table, see the section “[OUTSUM= Data Table](#)” on page 249.

SEVERITYMODEL Statement

```
SEVERITYMODEL severity-model-list < / definition-option > ;
```

The `SEVERITYMODEL` statement specifies one or more severity distribution models that you want to use in simulating a compound distribution sample. The *severity-model-list* is a space-separated list of names of severity models that you would use with PROC SEVSELECT’s `DIST` statement. The `SEVERITYEST=` data table or the `SEVERITYSTORE=` item store must contain all the severity models in the list. If you specify the `SEVERITYEST=` data table and you specify a name that does not appear in the `_MODEL_` column of the `SEVERITYEST=` data table, then that name is ignored. Similarly, if you specify the `SEVERITYSTORE=` item store and a severity model by that name does not appear in the item store, then that name is ignored.

You can also specify the following *definition-option* (after a slash) in the `SEVERITYMODEL` statement:

DEFINITIONSTABLE="CAS-table-name" <(CASLIB="caslib")>

SEVDEF="CAS-table-name" <(CASLIB="caslib")>

specifies a data table on the CAS server that contains the severity distribution function definitions. If you omit the CASLIB= option, then PROC CCDM assumes that the table is in the caslib that is active in the current CAS session. To specify a different caslib, use the CASLIB= option.

If you omit the DEFINITIONSTABLE= option, then PROC CCDM loads the severity function definitions from the library Sashelp.Svrtdist and the libraries that you specify in the CMPLIB= SAS system option, and it creates a temporary CAS table named cdm_svrtdist in the current CAS session. However, this process requires additional time and effort that you can avoid by specifying the DEFINITIONSTABLE= option. You can use the CAS table that the SEVSELECT procedure creates when it fits the severity models. For more information, see the OUTFUNCDEF= option in the DIST statement of the SEVSELECT procedure.

If you specify more than one SEVERITYMODEL statement, only the first one is used.

If you do not specify a SEVERITYMODEL statement, then this is equivalent to specifying all the severity models that appear in the SEVERITYEST= data table or the SEVERITYSTORE= item store.

A compound distribution sample is generated for each severity model by compounding that severity model with the frequency model that you specify in the COUNTSTORE= item store or the COUNTMODEL statement, or the external frequency model that is encoded by the COUNT= variable that you specify in the EXTERNALCOUNTS statement.

SIMULATEDSYMBOL Statement

SIMULATEDSYMBOL *symbol* ~ *distribution-name*(*parameter-value-list*) <... *symbol* ~ *distribution-name*(*parameter-value-list*)> ;

The SIMULATEDSYMBOL statement specifies one or more symbols and their associated probability distributions that you want PROC CCDM to simulate. You must use these symbols in the programming statements that define one or more of the ADJUSTEDSEVERITY= symbols. Hence, this statement is ignored if you do not specify the ADJUSTEDSEVERITY= option.

Each simulated *symbol* is a random variable that follows a specific parametric probability distribution, which you specify by using the *distribution-name* followed by a *parameter-value-list* that is enclosed in parentheses. The list of supported distributions is shown in Table 7.2 and Table 7.3 in the section “Fixed Parameter-Value Distributions” on page 240. The *distribution-name* is one of the names that appear in the Names column of those tables, and *parameter-value-list* is a comma- or space-separated list of numbers that represent the values of the parameters in the order in which the parameters appear top to bottom in the Parameters column for the specified *distribution-name* in those tables. The SIMULATEDSYMBOL statement can contain multiple such symbol specifications separated by a space.

The simulated symbols are useful in applications where your adjusted severity depends on some random variables that you have estimated externally. For example, if you are simulating the pure premium by specifying the SIMULATIONMODE=PP option, and if your frequency is modeled as the average number of claims per exposure, then to estimate the loss that you expect to pay for multiple exposures, you need to multiply the pure premium by the exposure. Typically, exposure is a random variable that you estimate externally by using a regression or time series forecasting technique. The SIMULATEDSYMBOL statement enables you to easily incorporate such stochastic variables in the simulation process. For example, if exposure

denotes the exposure and if you have estimated it to follow a normal distribution $\mathcal{N}(\mu = 100, \sigma = 7.5)$, then you can specify the following statements to instruct PROC CCDM to estimate the distribution of the paid loss (paidLoss) that accounts for the randomness of exposure:

```
proc ccdm severitystore=mylib.sevstore countstore=mylib.cntstore
    simulationmode=pp adjustedseverity=paidLoss;
    simulatedsymbol exposure ~ normal(100,7.5);
    paidLoss = _sev_ * exposure;
run;
```

Programming Statements

In PROC CCDM, you can use a series of programming statements that use variables in the DATA= data table to define multiple adjustments to an individual severity value. Each adjusted severity value is aggregated to form a separate adjusted compound distribution sample.

The programming statements are executed for each simulated individual severity value. The observation of the input data table that is used to evaluate the programming statements is determined by the simulation process that is described in the section “[Simulation Processes for Collective Risk Simulation Mode](#)” on page 217.

For more information, see the section “[Simulation of Adjusted Compound Distribution Sample](#)” on page 229.

Details: CCDM Procedure

Specifying Scenario Data in the DATA= Data Table

A scenario represents a state of the world for which you want to estimate the distribution of aggregate losses. The state consists of one or more entities that generate the loss events. For example, an entity might be an individual who has an insurance policy or an organization that has a workers’ compensation policy. Each entity has some characteristics of its own and some external factors that affect the frequency with which it generates the losses and the severity of each loss. For example, characteristics of an individual automobile insurance policyholder can include various demographics of the individual and various features of the automobile. Characteristics of an organization that has a workers’ compensation policy can be the number of employees, revenue, ratio of temporary to permanent employees, and so on. The organization can also be affected by external macroeconomic factors such as GDP and unemployment rate of the country where it operates and factors that affect its industry. You need to quantify and specify all these characteristics as external factors (regressors) when you fit severity and frequency models.

You should specify all the information about a scenario in the DATA= data table that you specify in the PROC CCDM statement. Each observation in the DATA= data table encodes the characteristics of an entity. For proper simulation of severities, you must specify in the DATA= data table all the characteristics that you use as regressors in the severity scale regression models. When you use the COUNTSTORE= option to specify the frequency model, you must specify in the DATA= data table all the characteristics that you use as regressors in the frequency model in order to properly simulate the counts. All the regressors are expected to

have nonmissing values. If any of the regressors have a missing value in an observation, then that observation is ignored.

The information in the DATA= data table is interpreted as follows, based on whether you specify the EXTERNALCOUNTS statement:

- If you do not specify the EXTERNALCOUNTS statement, then all the observations in the data table form a scenario. The observations are used together to compute one random draw from the compound distribution. The total number of draws is equal to the value that you specify in the NREPLICATES= option. The simulation process is described in the section “[Simulation with Regressors and No External Counts](#)” on page 218 and illustrated using an example in the section “[Illustration of Aggregate Loss Simulation Process](#)” on page 219.
- If you specify the EXTERNALCOUNTS statement, then the DATA= data table is expected to contain multiple replications (draws) of the frequency counts that you simulate externally for a scenario. The DATA= data table must contain the COUNT= variable that you specify in the EXTERNALCOUNTS statement. The replications are identified by the observation number or the ID= variable that you specify in the EXTERNALCOUNTS statement. For each observation in a given replication, the COUNT= variable is expected to contain the count of losses that are generated by the entity associated with that observation. All the observations of a given replication are used together to compute one random draw from the compound distribution. The size of the compound distribution sample is equal to the number of distinct replications that you specify in the DATA= data table, multiplied by the value that you specify in the NREPLICATES= option. The simulation process is described in the section “[Simulation with External Counts](#)” on page 221 and illustrated using an example in the section “[Illustration of the Simulation Process with External Counts](#)” on page 221.

In both cases, an observation can also contain severity adjustment variables that you can use to adjust the severity of the losses generated by that entity, based on some policy rules. For more information about simulating the adjusted compound distribution sample, see the section “[Simulation of Adjusted Compound Distribution Sample](#)” on page 229.

If you specify severity and frequency models that contain no regression effects, and if you do not specify externally simulated counts in the EXTERNALCOUNTS statement, then you do not need to specify the DATA= data table. This case corresponds to a fixed scenario that is represented entirely by the distribution parameters of the models.

Simulation Processes for Collective Risk Simulation Mode

This section describes the simulation processes for the collective risk mode, which is the simulation mode that PROC CCDM uses when you do not specify the SIMULATIONMODE= option or when you specify SIMULATIONMODE=CR. For other simulation modes, see the section “[Simulation Processes for Pure Premium and Custom Simulation Modes](#)” on page 225.

PROC CCDM selects a simulation process based on whether you specify external counts or you request that PROC CCDM simulate the counts and on whether or not the severity or frequency models contain regression effects. The following sections describe the processes for the different possibilities.

Simulation with No Regressors and No External Counts

If you specify severity and frequency models that contain no regression effects and if you do not specify externally simulated counts in the EXTERNALCOUNTS statement, then PROC CCDM uses the simulation process that this section describes.

The process is described for one severity distribution, *dist*. If you specify multiple severity distributions in the SEVERITYMODEL statement, then the process is repeated for each specified distribution.

The following steps are repeated M times to generate a compound distribution sample of size M , where M is the value of the NREPLICATES= option:

1. Use the frequency model that you specify in the COUNTSTORE= item store or the COUNTMODEL statement to draw a value N from the count distribution, where N denotes the number of loss events that are expected to occur in the time period that is being simulated. Adjust N to conform to the upper limit by setting it equal to $\min(N, N_{\max})$, where $N_{\max}$ is the value of the MAXCOUNTDRAW= option.
2. Use the parameter estimates of the severity distribution *dist* (which are read from the SEVERITYEST= data table or the SEVERITYSTORE= item store that you specify) to draw N severity values, X_j ($j = 1, \dots, N$). (For more information about how PROC CCDM draws an individual severity value, see the section “Making a Random Draw from a Severity Distribution” on page 224.)
3. Add the N severity values that are drawn in step 2 to compute one sample point, S , of the compound distribution sample as

$$S = \sum_{j=1}^N X_j$$

Although it is more common to fit a frequency model that contains regressors, the CNTSELECT procedure enables you to fit a frequency model that does not contain regressors. If you do not specify any regressors in the MODEL statement of PROC CNTSELECT, then it fits a model that contains only an intercept.

Simulation with Regressors and No External Counts

If the severity or frequency models contain regression effects and if you do not specify externally simulated counts in the EXTERNALCOUNTS statement, then you must specify a DATA= data table to provide values of the regression variables, which together represent a scenario for which you want to simulate the CDM. In this case, PROC CCDM uses the simulation process that this section describes.

The process is described for one severity distribution. If you specify multiple severity distributions in the SEVERITYMODEL statement, then the process is repeated for each specified distribution.

Note that you are performing scenario analysis when regression effects are present. Let K denote the number of observations that form the scenario. This is the number of observations either in the current BY group or in the entire DATA= data table if you do not specify the BY statement. If $K > 1$, then you are modeling the scenario for a group of entities. If $K = 1$, then you are modeling the scenario for one entity.

The following steps are repeated M times to generate a compound distribution sample of size M , where M is the value of the NREPLICATES= option:

1. For each observation k ($k = 1, \dots, K$), draw a count N_k from the frequency model, where N_k denotes the number of loss events that are expected to be generated by entity k in the time period that is being simulated. If you specify the COUNTSTORE= item store, then draw N_k from the frequency model whose parameters are determined by the frequency regressors in observation k . If you specify the COUNTMODEL statement, the frequency model does not depend on the regressors, so draw N_k by using the information in the COUNTMODEL statement. Adjust N_k to conform to the upper limit by setting it equal to $\min(N_k, N_{\max})$, where $N_{\max}$ is the value of the MAXCOUNTDRAW= option.
2. Add counts from all observations to compute $N = \sum_{k=1}^K N_k$, which is the total number of loss events that are expected to occur in the time period that is being simulated.
3. Make N random draws from the severity distribution and add them to generate one sample point of the compound distribution sample. If you specify a scale regression model for the severity distribution, then use the values of severity regressors in the k th observation to compute the scale parameter of the severity distribution and make N_k severity draws from that distribution. (For more information about how PROC CCDM makes a random severity draw, see the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.)

If you specify the BY statement, then a separate sample of size M is created for each BY group in the DATA= data table.

Illustration of Aggregate Loss Simulation Process

As an illustration of the simulation process, consider a very simple example of analyzing the distribution of an aggregate loss that is incurred by a set of policyholders of an automobile insurance company in a period of one year. It is postulated that the frequency and severity distributions depend on three variables: Age, Gender (1: female, 2: male), and CarType (1: sedan, 2: sport utility vehicle). So these variables are used as regressors while you fit the count model and severity scale regression model by using the CNTSELECT and SEVSELECT procedures, respectively. Now, consider that you want to use the fitted frequency and severity models to estimate the distribution of the aggregate loss that is incurred by a set of five policyholders. The characteristics of the five policyholders are encoded in a data table named mylib.Scenario that has the following contents:

Obs	age	gender	carType
1	30	2	1
2	25	1	2
3	45	2	2
4	33	1	1
5	50	1	1

The column Obs contains the observation number. It is shown only for the purpose of illustration. It does not need to be present in the data table. The following PROC CCDM step simulates the scenario in the data table mylib.Scenario:

```
proc ccdm data=mylib.scenario
    severityest=<severity parameter estimates data table>
    countstore=<count model store> nreplicates=<sample size>;
    severitymodel <severity distribution name(s)>;
run;
```

The following process generates a sample from the aggregate loss distribution for the scenario in the data table mylib.Scenario:

1. Use the values Age=30, Gender=2, and CarType=1 in the first observation to draw a count from the count distribution. Let that count be 2. Repeat the process for the remaining four observations. Let the counts be as shown in the Count column in the following table:

Obs	age	gender	carType	count
1	30	2	1	2
2	25	1	2	1
3	45	2	2	2
4	33	1	1	3
5	50	1	1	0

The Count column is shown for illustration only; it is not added as a variable to the DATA= data table.

2. The simulated counts from all the observations are added together to get a value of $N = 8$. This means that for this particular sample point, you expect a total of eight loss events in a year from these five policyholders.
3. For the first observation, the scale parameter of the severity distribution is computed by using the values Age=30, Gender=2, and CarType=1. That value of the scale parameter is used together with estimates of the other parameters from the SEVERITYEST= data table to make two draws from the severity distribution. Each draw simulates the magnitude of the loss that is expected from the first policyholder. The process is repeated for the remaining four policyholders. The fifth policyholder does not generate any loss event for this particular sample point, so no severity draws are made by using the fifth observation. Let the severity draws, rounded to integers for convenience, be as shown in the _SEV_ column in the following table:

Obs	age	gender	carType	count	_sev_		
1	30	2	1	2	350	2100	
2	25	1	2	1	4500		
3	45	2	2	2	700	4300	
4	33	1	1	3	600	1500	950
5	50	1	1	0			

The _SEV_ column is shown for illustration only; it is not added as a variable to the DATA= data table.

PROC CCDM adds the severity values of the eight draws to compute an aggregate loss value of 15,000. After recording this amount in the sample, the process returns to step 1 to compute the next point in the aggregate loss sample. For example, in the second iteration, the count distribution of each policyholder might generate one loss event, for a total of five loss events, and the five severity draws from the severity distributions that govern each policyholder might add up to 5,000. Then, the value of 5,000 is recorded as the second point in the aggregate loss sample. The process continues until M aggregate loss sample points are simulated, where the M is the value that you specify in the NREPLICATES= option.

Simulation with External Counts

If you specify externally simulated counts by using the `EXTERNALCOUNTS` statement, then each replication in the input data table represents the loss events that are generated by an entity. An entity can be an individual or organization for which you want to estimate the compound distribution. If an entity has any characteristics that are used as external factors (regressors) in developing the severity scale regression model, then you must specify the values of those factors in the `DATA=` data table. If you specify the `ID=` variable, then multiple observations for the same replication ID represent different entities in a group for which you are simulating the CDM.

This section describes the simulation process that `PROC CCDM` uses in the presence of externally simulated counts.

The process is described for one severity distribution. If you specify multiple severity distributions in the `SEVERITYMODEL` statement, then the process is repeated for each specified distribution.

Let there be M distinct replications in the current `BY` group of the `DATA=` data table or in the entire `DATA=` data table if you do not specify the `BY` statement. A replication is identified by either the observation number or the value of the `ID=` variable that you specify in the `EXTERNALCOUNTS` statement.

For each of the M values of the replication identifier, the following steps are executed R times, where R is the value of the `NREPLICATES=` option:

1. If there are K ($K \geq 1$) observations for the current value of the replication identifier, then for each observation k ($k = 1, \dots, K$), set N_k equal to the value of the `COUNT=` variable in that observation. Adjust N_k to conform to the upper limit by setting it equal to $\min(N_k, N_{\max})$, where $N_{\max}$ is the value of the `MAXCOUNTDRAW=` option.
2. Compute the total number of losses N across all observations of the replication as $N = \sum_{k=1}^K N_k$.
3. Make N random draws from the severity distribution and add them to generate one sample point of the compound distribution sample. If you specify a scale regression model for the severity distribution, then use the values of severity regressors in the k th observation to compute the scale parameter of the severity distribution and make N_k severity draws from that distribution. (For more information about how `PROC CCDM` makes a random severity draw, see the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.)

This process generates a compound distribution sample of size $M \times R$. If you specify the `BY` statement, then a separate sample of size $M \times R$ is created for each `BY` group in the `DATA=` data table.

Illustration of the Simulation Process with External Counts

To illustrate the simulation process, consider the following simple example. In this example, your severity model does not contain any regressors. An example that uses a severity scale regression model is illustrated later. Assume that you have made 10 random draws from an external count model and recorded them in the variable `ExtCount` of a data table named `mylib.Counts1`, as follows:

Obs	extCount
1	3
2	2
3	0
4	1

5	3
6	4
7	1
8	2
9	0
10	5

Because the data table does not contain an ID= variable, the observation number that is shown in the Obs column acts as the replicate identifier. The following PROC CCDM step simulates an aggregate loss sample by using the data table mylib.Counts1:

```
proc ccdm data=mylib.counts1 nreplicates=5
    severityest=<severity parameter estimates data table>;
    severitymodel <severity distribution name(s)>;
    externalcounts count=extCount;
run;
```

The simulation process works as follows:

1. For the first replication, which is associated with the first observation, three severity values are drawn from the severity distribution by using the parameter estimates that you specify in the SEVERITYEST= data table. If the severity values are 150, 500, and 320, then their sum of 970 is recorded as the first point of the aggregate loss sample. Because the value of the NREPLICATES= option is 5, this process of drawing three severity values and adding them together to form a point of the aggregate loss sample is repeated four more times to generate a total of five sample points that correspond to the first observation.
2. For the second replication, two severity values are drawn from the severity distribution. If the severity values are 450 and 100, then their sum of 550 is recorded as a point of the aggregate loss sample. This process of drawing two severity values and adding them together to form a point of the aggregate loss sample is repeated four more times to generate a total of five sample points that correspond to the second observation.
3. The process continues until all the replications, which are observations in this case, are exhausted.

The process results in an aggregate loss sample of size 50, which is equal to the number of replications in the data table (10) multiplied by the value of the NREPLICATES= option (5).

Now, consider an example in which the severity models in the SEVERITYEST= data table are scale regression models. In this case, the severity distribution that is used for drawing the severity value is determined by the values of regressors in the observation that is being processed. Consider that you want to simulate the aggregate loss that one policyholder incurs and you have recorded, in the variable ExtCount, the results of 10 random draws from an external count model. The DATA= data table has the following contents:

Obs	age	gender	carType	extCount
1	30	2	1	5
2	30	2	1	2
3	30	2	1	0
4	30	2	1	1
5	30	2	1	3
6	30	2	1	4
7	30	2	1	1

8	30	2	1	2
9	30	2	1	0
10	30	2	1	5

The simulation process in this case is the same as the process in the previous case of no regressors, except that the severity distribution that PROC CCDM uses for drawing the severity values has a scale parameter that is determined by the values of the regressors *Age*, *Gender*, and *CarType* in the observation that is being processed. In this particular example, all observations have the same value for all regressors, indicating that you are modeling a scenario in which the characteristics of the policyholder do not change during the time for which you have simulated the number of events. You can also model a scenario in which the characteristics of the policyholder change by recording those changes in the values of the appropriate regressors.

Extending this example further, consider that you want to analyze the distribution of the aggregate loss that is incurred by a group of policyholders, as in the example in the section “[Illustration of Aggregate Loss Simulation Process](#)” on page 219. Let the data table *mylib.Counts2* record multiple replications of the number of losses that each policyholder might generate. The contents of the data table *mylib.Counts2* are as follows:

Obs	replicateId	age	gender	carType	extCount
1	1	30	2	1	2
2	1	25	1	2	1
3	1	45	2	2	3
4	1	33	1	1	5
5	1	50	1	1	1
6	2	30	2	1	3
7	2	25	1	2	2
8	1	45	2	2	0
9	2	33	1	1	4
10	2	50	1	1	1

The variable *ReplicateId* records the identifier for the replication. Each replication contains multiple observations, such that each observation represents one of the policyholders that you are analyzing. For simplicity, only the first two replications are shown here.

The following PROC CCDM step simulates an aggregate loss sample by using the data table *mylib.Counts2*:

```
proc ccdm data=mylib.counts2 nreplicates=3
    severityest=<severity parameter estimates data table>;
    severitymodel <severity distribution name(s)>;
    externalcounts count=extCount id=replicateId;
    output out=aggloss samplevar=totalLoss;
run;
```

When you specify an *ID=* variable in the *EXTERNALCOUNTS* statement, the *DATA=* data table must be partitioned by the *ID=* variable as noted in the description of the *ID=* option.

The simulation process works as follows:

1. First, the five observations of the first replication (*ReplicateId*=1) are analyzed. For the first observation (*Obs*=1), the scale parameter of the severity distribution is computed by using the values *Age*=30, *Gender*=2, and *CarType*=1. That value of the scale parameter is used together with estimates of the other parameters from the *SEVERITYEST=* data table to make two draws from the severity distribution. Next, the regressor values of the second observation are used to compute the scale parameter of the severity distribution, which is used to make one severity draw. The process continues such that the

regressor values in the third, fourth, and fifth observations are used to select which severity distribution to make three, five, and one draws from, respectively. Let the severity values that are drawn from the observations of this replication be as shown in the `_SEV_` column in the following table, where the `_SEV_` column is shown for illustration only; it is not added as a variable to the `DATA=` data table.

Obs	replicateId	age	gender	carType	extCount	_sev_
1	1	30	2	1	2	700 500
2	1	25	1	2	1	5000
3	1	45	2	2	3	900 1400 300
4	1	33	1	1	5	350 2000 150 800 600
5	1	50	1	1	1	250

The values of all 12 severity draws are added together to compute and record the value of 12,950 as the first point of the aggregate loss sample. Because you specify `NREPLICATES=3` in the `PROC CCDM` step, this process of making 12 severity draws from the respective observations is repeated two more times to generate a total of three sample points for the first replication.

2. The five observations of the second replication (`ReplicateId=2`) are analyzed next to draw three, two, four, and one severity values from the severity distributions, with scale parameters that are determined by the regressor values in the sixth, seventh, ninth, and tenth observations, respectively. The 10 severity values are added together to form a point of the aggregate loss sample. This process of making 10 severity draws from the respective observations is repeated two more times to generate a total of three sample points for the second replication.

If your data table `mylib.Counts2` contains 10,000 distinct values of `ReplicateId`, then 30,000 observations are written to the data table `mylib.AgglLoss` that you specify in the `OUTPUT` statement of the preceding `PROC CCDM` step. Because you specify `SAMPLEVAR=TotalLoss` in the `OUTPUT` statement, the aggregate loss sample is available in the `TotalLoss` column of the data table `mylib.AgglLoss`.

Making a Random Draw from a Severity Distribution

`PROC CCDM` uses a simple process to make a random draw from the severity distribution. It first makes a draw from the uniform distribution. If this value is denoted by p , then the corresponding severity draw is computed as $x = F^{-1}(p)$, where F denotes the cumulative distribution function (CDF) of the severity distribution.

For a severity distribution *dist*, `PROC CCDM` computes the inverse of the CDF (that is, F^{-1}) by evaluating the `dist_QUANTILE` function. If `PROC CCDM` does not find the definition of the `dist_QUANTILE` function in the `DEFINITIONSTABLE=` table or in the libraries that you specify in the `CMPLIB=` system option, it uses a numerical inversion algorithm to invert the CDF function at p . This algorithm yields an approximate inverse and can be slow because it makes multiple calls to the `dist_CDF` or `dist_LOGCDF` function of the distribution. So it is recommended that you define the `dist_QUANTILE` function whenever possible for any custom severity distribution that you define for use with `PROC CCDM`. For more information about defining custom severity distributions, see the section “[Defining a Severity Distribution Model with the FCMP Procedure](#)” on page 1811 in Chapter 26, “[SEVSELECT Procedure](#).” The `dist_QUANTILE` function is already defined for all severity distributions in the library `Sashelp.Svrtdist`.

To evaluate the `dist_QUANTILE` or `dist_CDF` function, `PROC CCDM` uses the distribution parameters that it reads from the `SEVERITYEST=` data table or the `SEVERITYSTORE=` item store. If the severity model

contains regression effects, then PROC CCDM computes the scale parameter of the severity distribution by using the base value of the scale parameter and the values of the regression effects.

Making a Random Draw from a Truncated Severity Distribution

PROC CCDM assumes that the severity distribution that you specify in the `SEVERITYEST=` data table or the `SEVERITYSTORE=` item store is an untruncated distribution—that is, a distribution that has the full support. For severity distributions that have a scale parameter, full support is $[0, \infty)$, and for severity distributions that have a log-scale parameter, full support is $(-\infty, \infty)$. If you want PROC CCDM to make draws from a truncated distribution, which is especially useful in insurance applications, then you can specify the `LEFTTRUNCATION=` or `RIGHTTRUNCATION=` options in the PROC CCDM statement.

Let L and R denote the left-truncation threshold and right-truncation limit that you specify in the `LEFTTRUNCATION=` and `RIGHTTRUNCATION=` options, respectively. Let F and $F_{L,R}$ denote the cumulative distribution functions (CDF) of the untruncated and truncated severity distributions, respectively. Not specifying the `LEFTTRUNCATION=` option is equivalent to specifying $L = F^{-1}(0)$ —that is, $F(L) = 0$. Not specifying the `RIGHTTRUNCATION=` option is equivalent to specifying $R = F^{-1}(1)$ —that is, $F(R) = 1$.

PROC CCDM makes a random draw from the truncated severity distribution by using the following steps:

1. Draw a value p_t from the uniform distribution. This is the CDF of the truncated distribution.
2. Compute p , which represents the CDF of the untruncated distribution, as

$$p = p_t(F(R) - F(L)) + F(L)$$

3. Compute the severity value x by inverting the CDF of the untruncated distribution as $x = F^{-1}(p)$. The value of x that is computed in this manner is essentially a random draw from $F_{L,R}$ —that is, $x = F_{L,R}^{-1}(p_t)$. The inversion of the untruncated CDF is described in the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.

Simulation Processes for Pure Premium and Custom Simulation Modes

This section describes the simulation processes for pure premium mode (when you specify `SIMULATIONMODE=PP`) and custom mode (when you specify `SIMULATIONMODE=CUSTOM`).

Like the simulation processes for the collective risk mode, which are described in the section “[Simulation Processes for Collective Risk Simulation Mode](#)” on page 217, the simulation processes for pure premium and custom modes also depend on whether you specify external counts or you request that PROC CCDM simulate the counts and on whether or not the severity or frequency models contain regression effects. The following sections describe the processes for the different possibilities.

Simulation with No Regressors and No External Counts

If you specify severity and frequency models that contain no regression effects and if you do not specify externally simulated counts in the EXTERNALCOUNTS statement, then PROC CCDM uses the simulation process that this section describes.

The process is described for one severity distribution, *dist*. If you specify multiple severity distributions in the SEVERITYMODEL statement, then the process is repeated for each specified distribution. Let D denote the number of adjusted severity symbols that you specify in the ADJUSTEDSEVERITY= option.

The following steps are repeated M times to generate a compound distribution sample of size M , where M is the value of the NREPLICATES= option:

1. Use the frequency model that you specify in the COUNTSTORE= item store or the COUNTMODEL statement to draw a value N from the count distribution.
2. Use the parameter estimates of the severity distribution *dist* (which are read from the SEVERITYEST= data table or the SEVERITYSTORE= item store that you specify) to draw a severity value X . (For more information about how PROC CCDM draws an individual severity value, see the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.)
3. Compute one sample point of different aggregate loss samples as follows:
 - For SIMULATIONMODE=CUSTOM, do not compute the unadjusted aggregate loss sample point. Because D must be nonzero for this mode, compute D sample points S^d of the D adjusted aggregate loss samples as follows:
 - a) Set the _FREQ_ and _SEV_ placeholder symbols equal to N and X , respectively. (For more information about the placeholder symbols, see the section “[Simulation of Adjusted Compound Distribution Sample](#)” on page 229.)
 - b) Execute your severity adjustment program.
 - c) Retrieve the adjusted severity values X_k^d ($d = 1, \dots, D$) that your adjustment program computes.
 - d) Set the sample point S^d of the d th adjusted aggregate loss sample equal to X_k^d ($d = 1, \dots, D$).
 - For SIMULATIONMODE=PUREPREMIUM, multiply the frequency and severity values to compute the sample point S of the unadjusted aggregate loss sample as $S = NX$. If $D > 0$, then follow the same steps as the custom mode to compute D sample points S^d of the D adjusted aggregate loss samples, except for the following two differences:
 - Do not fill the _FREQ_ placeholder symbol, because it is valid only in the custom mode.
 - Compute S^d as $S^d = NX^d$ ($d = 1, \dots, D$).

Simulation with Regressors and No External Counts

If the severity or frequency models contain regression effects and if you do not specify externally simulated counts in the EXTERNALCOUNTS statement, then you must specify a DATA= data table to provide values of the regression variables, which together represent a scenario for which you want to simulate the CDM. In this case, PROC CCDM uses the simulation process that this section describes.

The process is described for one severity distribution. If you specify multiple severity distributions in the SEVERITYMODEL statement, then the process is repeated for each specified distribution. Let D denote the number of adjusted severity symbols that you specify in the ADJUSTEDSEVERITY= option.

Note that you are performing scenario analysis when regression effects are present. Let K denote the number of observations that form the scenario. This is the number of observations either in the current BY group or in the entire DATA= data table if you do not specify the BY statement. If $K > 1$, then you are modeling the scenario for a group of entities. If $K = 1$, then you are modeling the scenario for one entity.

The following steps are repeated M times to generate a compound distribution sample of size M , where M is the value of the NREPLICATES= option:

1. For each observation k ($k = 1, \dots, K$), draw a value N_k from the frequency model. If you specify the COUNTSTORE= item store, then the parameters of the frequency model are determined by the frequency regressors in observation k . If you specify the COUNTMODEL statement, the frequency model does not depend on the regressors, so N_k is drawn by using the information that you specify in the COUNTMODEL statement.
2. For each observation k ($k = 1, \dots, K$), draw a severity value X_k from the severity model. If you specify a scale regression model for the severity distribution, then the scale parameter of the severity distribution is determined by the values of the severity regressors in the k th observation. (For more information about how PROC CCDM makes a random severity draw, see the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.)
3. Compute one sample point of different aggregate loss samples as follows:
 - For SIMULATIONMODE=CUSTOM, do not compute the unadjusted aggregate loss sample point. Because D must be nonzero for this mode, compute D sample points S^d of the D adjusted aggregate loss samples as follows:
 - a) Execute your severity adjustment program K times, once per observation. To execute the program for the k th observation, set the _FREQ_ and _SEV_ placeholder symbols equal to N_k and X_k , respectively. (For more information about the placeholder symbols, see the section “[Simulation of Adjusted Compound Distribution Sample](#)” on page 229.)
 - b) Retrieve the adjusted severity values X_k^d ($d = 1, \dots, D$) that your adjustment program computes.
 - c) After all K observations are processed, compute the sample point S^d of the d th adjusted aggregate loss sample as $S^d = \sum_{k=1}^K X_k^d$ ($d = 1, \dots, D$).
 - For SIMULATIONMODE=PUREPREMIUM, compute the sample point S of the unadjusted aggregate loss sample as $S = \sum_{k=1}^K N_k X_k$. If $D > 0$, then follow the same steps as the custom mode to compute D sample points S^d of the D adjusted aggregate loss samples, except for the following two differences:
 - Do not fill the _FREQ_ placeholder symbol, because it is valid only in the custom mode.

- Compute S^d as $S^d = \sum_{k=1}^K N_k X_k^d$ ($d = 1, \dots, D$).

If you specify the BY statement, then a separate sample of size M is created for each BY group in the DATA= data table.

Simulation with External Counts

If you specify externally simulated counts by using the EXTERNALCOUNTS statement, then each replication in the input data table represents the loss events that are generated by an entity. An entity can be an individual or organization for which you want to estimate the compound distribution. If an entity has any characteristics that are used as external factors (regressors) in developing the severity scale regression model, then you must specify the values of those factors in the DATA= data table. If you specify the ID= variable, then multiple observations for the same replication ID represent different entities in a group for which you are simulating the CDM.

This section describes the simulation process that PROC CCDM uses in the presence of externally simulated counts.

The process is described for one severity distribution. If you specify multiple severity distributions in the SEVERITYMODEL statement, then the process is repeated for each specified distribution. Let D denote the number of adjusted severity symbols that you specify in the ADJUSTEDSEVERITY= option.

Suppose there are M distinct replications in the current BY group of the DATA= data table or in the entire DATA= data table if you do not specify the BY statement. A replication is identified either by the observation number or by the value of the ID= variable that you specify in the EXTERNALCOUNTS statement.

For each of the M values of the replication identifier, the following steps are executed R times, where R is the value of the NREPLICATES= option:

1. Read the value of the COUNT= variable, N_k , for each observation k ($k = 1, \dots, K$), where K denotes the number of observations in the current replication—that is, the number of observations in which the replication identifier has the same value.
2. For each observation k ($k = 1, \dots, K$), draw a severity value X_k from the severity model. If you specify a scale regression model for the severity distribution, then the scale parameter of the severity distribution is determined by the values of the severity regressors in the k th observation. (For more information about how PROC CCDM makes a random severity draw, see the section “[Making a Random Draw from a Severity Distribution](#)” on page 224.)
3. Compute one sample point of different aggregate loss samples as follows:
 - For SIMULATIONMODE=CUSTOM, do not compute the unadjusted aggregate loss sample point. Because D must be nonzero for this mode, compute D sample points S^d of the D adjusted aggregate loss samples as follows:
 - a) Execute your severity adjustment program K times, once per observation. To execute the program for the k th observation, set the _FREQ_ and _SEV_ placeholder symbols equal to N_k and X_k , respectively. (For more information about the placeholder symbols, see the section “[Simulation of Adjusted Compound Distribution Sample](#)” on page 229.)
 - b) Retrieve the adjusted severity values X_k^d ($d = 1, \dots, D$) that your adjustment program computes.

- c) After all K observations are processed, compute the sample point S^d of the d th adjusted aggregate loss sample as $S^d = \sum_{k=1}^K X_k^d$ ($d = 1, \dots, D$).
- For SIMULATIONMODE=PUREPREMIUM, compute the sample point S of the unadjusted aggregate loss sample as $S = \sum_{k=1}^K N_k X_k$. If $D > 0$, then follow the same steps as the custom mode to compute D sample points S^d of the D adjusted aggregate loss samples, except for the following two differences:
 - Do not fill the _FREQ_ placeholder symbol, because it is valid only in the custom mode.
 - Compute S^d as $S^d = \sum_{k=1}^K N_k X_k^d$ ($d = 1, \dots, D$).

This process generates a compound distribution sample of size $M \times R$. If you specify the BY statement, then a separate sample of size $M \times R$ is created for each BY group in the DATA= data table.

Simulation of Adjusted Compound Distribution Sample

If you specify a list of D adjusted severity symbols in the ADJUSTEDSEVERITY= option and specify programming statements that compute those symbols, then a separate compound distribution sample is generated for each adjusted severity symbol. The set of all programming statements that you specify in the PROC CCDM step is called the severity adjustment program.

Formally, the severity adjustment program is expected to implement D adjustment functions for all D adjusted severity symbols. The adjustment function for the d th symbol is denoted by f^d ($d = 1, \dots, D$). The function f^d uses the unadjusted severity value, X_j along with other values, some of which depend on the simulation mode, to compute and return an adjusted severity value, X_j^d . The information that is available to compute X_j^d depends on the simulation mode as follows:

- For the collective risk simulation mode, if N denotes the number of loss events that are simulated for the current replication of the simulation process, then for the severity draw, X_j , of the j th loss event ($j = 1, \dots, N$), the adjusted severity value for the d th symbol is

$$X_j^d = f^d(X_j, S_{j-1}, S_{j-1}^d, \Psi_j)$$

where $S_{j-1} = \sum_{l=1}^{j-1} X_l$ is the aggregate unadjusted loss, $S_{j-1}^d = \sum_{l=1}^{j-1} X_l^d$ is the aggregate value of the d th adjusted severity symbol before the j th severity draw that generates X_j , and Ψ_j denotes the vector of values of the stochastic symbols that you specify in the SIMULATEDSYMBOL statement. The initial values of both S and S^d are set to 0—that is, $S_0 = 0$ and $S_0^d = 0$ ($d = 1, \dots, D$). Prior to executing your adjustment program, PROC CCDM makes a random draw for each stochastic symbol by using that symbol's probability distribution and parameter values. The aggregate adjusted loss for the replication is S_N^d , which is denoted by S^d for simplicity and is defined as

$$S^d = \sum_{j=1}^N X_j^d$$

- For pure premium and custom simulation modes, there is only one severity draw for every frequency draw, so the index j is always equal to 1.

- For pure premium mode, the adjusted severity value depends only on the unadjusted severity value and stochastic symbols as $X_1^d = f^d(X_1, \Psi_1)$ and the aggregate adjusted loss for the replication is $S^d = NX_1^d$.
- For custom simulation mode, you are free to combine the values of frequency, severity, and stochastic symbols in any manner to compute the adjusted severity value as $X_1^d = f^d(N, X_1, \Psi_1)$ and PROC CCDM sets the aggregate adjusted loss equal to the adjusted severity value as $S^d = X_1^d$.

In your severity adjustment program, you can use the following keywords as placeholder symbols for the input arguments of the function f^d :

_ADJSEVSUM d _

_CUMADJSEV d _

indicates the placeholder for S_{j-1}^d , the sum of adjusted severity values for the d th symbol that are computed by your program before X_j is generated and adjusted. PROC CCDM supplies this value to your program. For $d = 1$, you can use the symbol _ADJSEVSUM_ (alias _CUMADJSEV_).

This placeholder is always meaningful for **SIMULATIONMODE=COLLECTIVERISK**, but for **SIMULATIONMODE=PUREPREMIUM** and **SIMULATIONMODE=CUSTOM**, it is meaningful only for a multi-entity scenario, which is described in the section “[Aggregate Adjusted Loss Simulation for a Multi-entity Scenario](#)” on page 231.

FREQ

indicates the placeholder for frequency N . PROC CCDM supplies this value to your program.

You can use this placeholder only when you specify **SIMULATIONMODE=CUSTOM**.

SEV

indicates the placeholder for X_j , the unadjusted severity value. PROC CCDM generates this value as described in the section “[Simulation with No Regressors and No External Counts](#)” on page 218 (step 2) or the section “[Simulation with Regressors and No External Counts](#)” on page 218 (step 3). PROC CCDM supplies this value to your program.

You can use this placeholder for all simulation modes.

SEVSUM

CUMSEV

indicates the placeholder for S_{j-1} , the sum of unadjusted severity values that PROC CCDM generates before X_j is generated. PROC CCDM supplies this value to your program.

This placeholder is always meaningful for **SIMULATIONMODE=COLLECTIVERISK**, but for **SIMULATIONMODE=PUREPREMIUM** and **SIMULATIONMODE=CUSTOM**, it is meaningful only for a multi-entity scenario, which is described in the section “[Aggregate Adjusted Loss Simulation for a Multi-entity Scenario](#)” on page 231.

Your severity adjustment program must assign the output of the d th function f^d to the d th symbol that you specify in the **ADJUSTEDSEVERITY=** option in the PROC CCDM statement. PROC CCDM uses the final assigned value of the d th symbol as the value of X_j^d .

You can use most DATA step statements and functions in your program. The DATA step file and the data table I/O statements (for example, INPUT, FILE, SET, and MERGE) are not available. However, some

functionality of the PUT statement is supported. For more information, see the section “PROC FCMP and DATA Step Differences” in *Base SAS Procedures Guide*.

The simulation process that generates the aggregate adjusted loss sample is identical to the process that is described in the section “Simulation with Regressors and No External Counts” on page 218 or the section “Simulation with External Counts” on page 221, except that after making each of the N severity draws, PROC CCDM executes your severity adjustment program to compute the adjusted severity symbols (X_j^d). All the N adjusted severity values are added together to compute S^d , which forms one point of the d th aggregate adjusted loss sample. The process is illustrated using an example in the section “Illustration of the Aggregate Adjusted Loss Simulation Process” on page 233.

Using Severity Adjustment Variables

If you do not specify the DATA= data table, then your ability to adjust the severity value is limited, because you can use only the current severity draw, sums of unadjusted and adjusted severity draws that are made before the current draw, and some constant numbers to encode your adjustment policy. That is sufficient if you want to estimate the distribution of aggregate adjusted loss for only one entity. However, if you are simulating a scenario that contains more than one entity, then it might be more useful if the adjustment policy depends on factors that are specific to each entity that you are simulating. To do that, you must specify the DATA= data table and encode such factors as *adjustment variables* in the DATA= data table. If A denotes the set of values of the adjustment variables, then each adjustment function f^d accepts the set A as one of its inputs, in addition to the other input values that it accepts according to the simulation mode. PROC CCDM reads the values of adjustment variables from the DATA= data table and supplies the set of those values (A) to your severity adjustment program. For an invocation of each f^d with an unadjusted severity value of X_j , the values in set A are read from the same observation that is used to simulate X_j .

All adjustment variables that you use in your program must be present in the DATA= data table. You must not use any keyword for a placeholder symbol as a name of any variable in the DATA= data table, whether the variable is a severity adjustment variable or a regressor in the frequency or severity model. Further, the following restrictions apply to the adjustment variables in your severity adjustment program:

- You can use only numeric-valued variables. This restriction also implies that you cannot use SAS functions or call routines that require character-valued arguments, unless you pass those arguments as constant (literal) strings or characters.
- You cannot use functions that create lagged versions of a variable. If you need lagged versions, then you can use a DATA step before the PROC CCDM step to add those versions to the input data table.

The use of adjustment variables is illustrated using an example in the section “Illustration of the Aggregate Adjusted Loss Simulation Process” on page 233.

Aggregate Adjusted Loss Simulation for a Multi-entity Scenario

If you are simulating a scenario that consists of multiple entities, then you can use some additional pieces of information in your severity adjustment program. Let the scenario consist of K entities, and let N_k denote the number of loss events that are incurred by the k th entity ($k = 1, \dots, K$) in the current iteration of the simulation process. The simulation mode determines the processing of multiple entities as follows:

- For the collective risk simulation mode, each value of N_k is adjusted to conform to the upper limit that is imposed by the value of the MAXCOUNTDRAW= option. The total number of severity draws that

need to be made is $N = \sum_{k=1}^K N_k$. The d th aggregate adjusted loss is now defined as

$$S^d = \sum_{k=1}^K \sum_{j=1}^{N_k} X_{k,j}^d$$

where $X_{k,j}^d$ is an adjusted severity value of the d th symbol for the k th entity in the j th draw ($j = 1, \dots, N_k$). The form of the adjustment function f^d that computes $X_{k,j}^d$ is

$$X_{k,j}^d = f^d(X_{k,j}, S_{k,j-1}, S_{k,j-1}^d, S_{n-1}, S_{n-1}^d, \Psi_{k,j}, A_k)$$

where $X_{k,j}$ is the value of the j th draw of unadjusted severity for the k th entity; $S_{k,j-1} = \sum_{l=1}^{j-1} X_{k,l}$ and $S_{k,j-1}^d = \sum_{l=1}^{j-1} X_{k,l}^d$ are the aggregate unadjusted loss and the aggregate adjusted loss, respectively, for the k th entity before $X_{k,j}$ is generated; $\Psi_{k,j}$ denotes the vector of values of the j th draw of stochastic symbols that you specify in the **SIMULATEDSYMBOL** statement for the k th entity; and A_k is the set of values of the severity adjustment variables that PROC CCDM reads from the DATA= data table for the k th entity.

The index n ($n = 1, \dots, N$) keeps track of the total number of severity draws, across all entities, that are made before $X_{k,j}$ is generated. So $S_{n-1} = \sum_{m=1}^{k-1} \sum_{l=1}^{N_m} X_{m,l} + \sum_{l=1}^{j-1} X_{k,l}$ and $S_{n-1}^d = \sum_{m=1}^{k-1} \sum_{l=1}^{N_m} X_{m,l}^d + \sum_{l=1}^{j-1} X_{k,l}^d$ are the aggregate unadjusted loss and aggregate adjusted loss, respectively, for all the entities that are processed before $X_{k,j}$ is generated. Note that S_{n-1} and S_{n-1}^d include the $j - 1$ draws that are made for the k th entity before $X_{k,j}$ is generated.

The initial values of all types of aggregate losses are set to 0. In other words, $S_0 = 0$; for all values of d , $S_0^d = 0$; for all values of k , $S_{k,0} = 0$; and for all combinations of k and d , $S_{k,0}^d = 0$.

In your severity adjustment program, you can use the following two additional placeholder keywords:

SEVSUMFOROBS

CUMSEVFOROBS

indicates the placeholder for $S_{k,j-1}$, which is the total loss that the k th entity incurs before the current loss event. PROC CCDM supplies this value to your program.

ADJSEVSUMFOROBSd

CUMADJSEVFOROBSd

indicates the placeholder for $S_{k,j-1}^d$, which is the total adjusted loss for the d th symbol that the k th entity incurs before the current loss event. PROC CCDM supplies this value to your program. For $d = 1$, you can use the symbol **_ADJSEVSUMFOROBS_** (alias **_CUMADJSEVFOROBS_**).

The previously described placeholder symbols **_SEVSUM_** and **_ADJSEVSUM_** represent S_{n-1} and S_{n-1}^d , respectively. If you have only one entity in the scenario ($K = 1$), then the values of **_SEVSUMFOROBS_** and **_ADJSEVSUMFOROBSd_** are identical to the values of **_SEVSUM_** and **_ADJSEVSUMd_**, respectively.

- For pure premium and custom simulation modes, there is one frequency draw per entity and only one severity draw for every frequency draw, so the index j is always equal to 1. PROC CCDM draws the frequency value N_k for each entity k and uses it according to the simulation mode as follows:

- For the pure premium simulation mode, the form of the adjustment function f^d that computes $X_{k,1}^d$ is

$$X_{k,1}^d = f^d(X_{k,1}, S_{n-1}, S_{n-1}^d, \Psi_{k,1}, A_k)$$

and PROC CCDDM computes the aggregate adjusted loss as

$$S^d = \sum_{k=1}^K N_k X_{k,1}^d$$

- For the custom simulation mode, you are free to combine the values of frequency, severity, stochastic symbols, and the adjustment variables in any manner to compute the adjusted severity value $X_{k,1}^d$. The form of the adjustment function f^d that computes $X_{k,1}^d$ is

$$X_{k,1}^d = f^d(N_k, X_{k,1}, S_{n-1}, S_{n-1}^d, \Psi_{k,1}, A_k)$$

and PROC CCDDM computes the aggregate adjusted loss as

$$S^d = \sum_{k=1}^K X_{k,1}^d$$

For both the pure premium and custom simulation modes, your adjustment program can use the previously described placeholder symbols `_SEVSUM_` and `_ADJSEVSUM_` to represent S_{n-1} and S_{n-1}^d , respectively.

Your severity adjustment program must implement all D adjustment functions and assign the output of the d th function f^d to the d th adjusted severity symbol that you specify in the `ADJUSTEDSEVERITY=` option. PROC CCDDM executes the severity adjustment program for each j th severity value that it draws for each k th entity, and it uses the final value of the d th symbol as the value of $X_{k,j}^d$.

There is one caveat when a scenario consists of more than one entity ($K > 1$) and when you use any of the symbols for cumulative severity values (`_SEVSUM_`, `_ADJSEVSUMd_`, `_SEVSUMFOROBS_`, or `_ADJSEVSUMFOROBSd_`) in your severity adjustment program. In this case, to make the simulation realistic, it is important to randomize the order of N severity draws across K entities. For more information, see the section “Randomizing the Order of Severity Draws across Observations of a Scenario” on page 236.

Illustration of the Aggregate Adjusted Loss Simulation Process

This section continues the example in the section “Simulation with Regressors and No External Counts” on page 218 to illustrate the simulation of aggregate adjusted loss for the collective risk simulation mode.

Recall that the earlier example simulates a scenario that consists of five policyholders. Assume that you want to compute the distribution of the aggregate amount paid to all the policyholders in a year, where the payment for each loss is determined by a deductible and a per-payment limit. To begin with, you must record the deductible and limit information in the input `DATA=` data table. The following table shows the `DATA=` data table from the earlier example, extended to include two variables, `Deductible` and `Limit`:

Obs	age	gender	carType	deductible	limit
1	30	2	1	250	5000
2	25	1	2	500	3000
3	45	2	2	100	2000
4	33	1	1	500	5000
5	50	1	1	200	2000

The variables Deductible and Limit are referred to as severity adjustment variables, because you need to use them to compute the adjusted severity. Let AmountPaid represent the value of adjusted severity that you are interested in. Further, let the following SAS programming statements encode your logic of computing the value of AmountPaid:

```
amountPaid = MAX(_sev_ - deductible, 0);
amountPaid = MIN(amountPaid, MAX(limit - _adjsevsumforobs_, 0));
```

PROC CCDM supplies your program with values of the placeholder symbols `_SEV_` and `_ADJSEVSUMFOROBS_`, which represent the value of the current unadjusted severity draw and the sum of adjusted severity values from the previous draws, respectively, for the observation that is being processed. The use of `_ADJSEVSUMFOROBS_` helps you ensure that the payment that is made to a particular policyholder in a year does not exceed the limit that is recorded in the variable Limit.

To simulate a sample for the aggregate of AmountPaid, you need to submit a PROC CCDM step whose structure is like the following:

```
proc ccdm data=<data table name> adjustedseverity=amountPaid
    severityest=<severity parameter estimates data table>
    countstore=<count model store>;
    severitymodel <severity distribution name(s)>;

    amountPaid = MAX(_sev_ - deductible, 0);
    amountPaid = MIN(amountPaid, MAX(limit - _adjsevsumforobs_, 0));
run;
```

The simulation process of one replication that generates one point of the aggregate loss sample and the corresponding point of the aggregate adjusted loss sample is as follows:

1. Use the values Age=30, Gender=2, and CarType=1 in the first observation to draw a count from the count distribution. Let that count be 3. Repeat the process for the remaining four observations. Let the counts be as shown in the Count column in the following table:

Obs	age	gender	carType	deductible	limit	count
1	30	2	1	250	5000	2
2	25	1	2	500	3000	1
3	45	2	2	100	2000	2
4	33	1	1	500	5000	3
5	50	1	1	200	2000	0

The Count column is shown for illustration only; it is not added as a variable to the DATA= data table.

2. The simulated counts from all the observations are added together to get a value of $N = 8$. This means that for this particular replication, you expect a total of eight loss events in a year from these five policyholders.

3. For the first observation, the scale parameter of the severity distribution is computed by using the values Age=30, Gender=2, and CarType=1. That value of the scale parameter is used together with estimates of the other parameters from the SEVERITYEST= data table to make two draws from the severity distribution. The process is repeated for the remaining four policyholders. The fifth policyholder does not generate any loss event for this particular replication, so no severity draws are made by using the fifth observation. Let the severity draws, rounded to integers for convenience, be as shown in the `_SEV_` column in the following table:

Obs	age	gender	carType	deductible	limit	count	<code>_sev_</code>		
1	30	2	1	250	5000	2	350	2100	
2	25	1	2	500	3000	1	4500		
3	45	2	2	100	2000	2	700	4300	
4	33	1	1	200	5000	3	600	1500	950
5	50	1	1	200	2000	0			

The `_SEV_` column is shown for illustration only; it is not added as a variable to the DATA= data table. The sample point for the aggregate unadjusted loss is computed by adding together the severity values of eight draws, which gives an aggregate loss value of 15,000. The aggregate unadjusted loss is also referred to as the ground-up loss.

For each severity draw, your severity adjustment program is executed to compute the adjusted severity, which is the value of AmountPaid in this case. For the draws in the preceding table, the values of AmountPaid are as follows:

Obs	deductible	limit	<code>_sev_</code>	<code>_adjsevsumforobs_</code>	amountPaid
1	250	5000	350	0	100
1	250	5000	2100	100	1850
2	500	3000	4500	0	3000
3	100	2000	700	0	600
3	100	2000	4300	600	1400
4	200	5000	600	0	400
4	200	5000	1500	400	1300
4	200	5000	950	1700	750

The adjusted severity values are added together to compute the cumulative payment value of 9,400, which forms the first sample point for the aggregate adjusted loss.

After recording the aggregate unadjusted and aggregate adjusted loss values in their respective samples, the process returns to step 1 to compute the next sample point unless the specified number of sample points have been simulated.

In this particular example, you can verify that the order in which the eight loss events are simulated does not affect the aggregate adjusted loss. As a simple example, consider the following order of draws, which is different from the consecutive order that the preceding table uses:

Obs	deductible	limit	<code>_sev_</code>	<code>_adjsevsumforobs_</code>	amountPaid
4	200	5000	600	0	400
3	100	2000	4300	0	2000
1	250	5000	350	0	100
3	100	2000	700	2000	0
4	200	5000	950	400	750

1	250	5000	2100	100	1850
2	500	3000	4500	0	3000
4	200	5000	1500	1150	1300

Although the payments that are made for individual loss events differ, the aggregate adjusted loss is still 9,400.

However, in general, when you use a cumulative severity value such as `_ADJSEVSUMFOROBS_` in your program, the order in which the draws are processed affects the final value of aggregate adjusted loss. For more information, see the sections “[Randomizing the Order of Severity Draws across Observations of a Scenario](#)” on page 236 and “[Illustration of the Need to Randomize the Order of Severity Draws](#)” on page 237.

Randomizing the Order of Severity Draws across Observations of a Scenario

If you specify a scenario that consists of more than one entity, then it is assumed that each entity generates its loss events independently from the other entities. In other words, the time at which the loss event of one entity is generated or recorded is independent of the time at which the loss event of another entity is generated or recorded. To honor this assumption of independence among entities, the order in which those entities are processed must be randomized across K entities such that no entity is preferred over another. The K entities are represented by K observations of the scenario in the `DATA=` data table. If you specify external counts, the K observations correspond to the observations that have the same replication identifier value. If you do not specify the external counts, then the K observations correspond to all the observations in the `BY` group, or to all the observations in the entire `DATA=` data table if you do not specify the `BY` statement.

The randomization process depends on the simulation mode:

- For the collective risk simulation mode, if entity k generates N_k loss events, where N_k is adjusted to conform to the upper limit that is imposed by the value of the `MAXCOUNTDRAW=` option, then the total number of loss events for a group of K entities is $N = \sum_{k=1}^K N_k$. To simulate the aggregate loss for this group, N severity draws are made and aggregated to compute one point of the compound distribution sample. To honor the assumption of independence among entities, the order of those N severity draws must be randomized across K entities such that no entity is preferred over another.

PROC CCDM implements the randomization process over N severity draws as follows: First, it chooses one of the K observations at random, say the k th observation, and draws one severity value ($X_{k,j}$) from the severity distribution that is implied by that observation. It then supplies the severity value, along with the values of the severity adjustment variables (A_k) and random draws of simulated symbols ($\Psi_{k,j}$), to your severity adjustment program to compute the adjusted severity values ($X_{k,j}^d$) and updates the respective aggregate adjusted losses (S^d). Next, it chooses another observation at random, draws one severity value from its implied severity distribution, and repeats the analysis of computing $X_{k,j}^d$ and updating S^d . In each step, PROC CCDM increments by 1 the total number of events that are simulated for the selected observation k . When it simulates all N_k events for an observation k , it retires that observation and continues the process with the remaining observations until it makes a total of N severity draws.

- For pure premium and custom simulation modes, there is one frequency and severity draw per entity. To honor the assumption of independence among entities, PROC CCDM randomizes the order in which it processes the entities as follows: First, it chooses one of the K observations at random, say the k th observation. It draws one frequency value and one severity value from the count and severity

distributions, respectively, that are implied by the k th observation. It then supplies those frequency (N_k) and severity ($X_{k,1}$) values, along with the values of the severity adjustment variables (A_k) and random draws of simulated symbols ($\Psi_{k,1}$), to your severity adjustment program to compute the adjusted severity values ($X_{k,1}^d$) and updates the respective aggregate adjusted losses (S^d). Next, PROC CCDM retires the processed observation, chooses another observation at random from the remaining $K - 1$ observations, and repeats the analysis of computing $X_{k,1}^d$ and updating S^d . The process continues until all K observations are exhausted.

The randomization process is especially important in the context of simulating an adjusted compound distribution sample when your severity adjustment program uses the aggregate adjusted severity to adjust the next severity value. For an illustration of the need to randomize in such cases for the collective risk simulation mode, see the next section.

Illustration of the Need to Randomize the Order of Severity Draws

This section uses the example in the section “[Illustration of the Aggregate Adjusted Loss Simulation Process](#)” on page 233, but with the following PROC CCDM step:

```
proc ccdm data=<data table name> adjustedseverity=amountPaid
    severityest=<severity parameter estimates data table>
    countstore=<count model store>;
    severitymodel <severity distribution name(s)>;

    if (_adjsevsum_ > 15000) then
        amountPaid = 0;
    else do;
        penaltyFactor = MIN(3, 15000/(15000 - _adjsevsum_));
        amountPaid = MAX(0, _sev_ - deductible * penaltyFactor);
    end;
run;
```

The severity adjustment statements in the preceding code compute the value of AmountPaid by using the collective risk simulation mode and the following provisions in the insurance policy:

- There is a limit of 15,000 on the total amount that can be paid in a year to the group of policyholders that is being simulated. The amount of payment for each loss event depends on the total amount of payments before that loss event.
- The penalty for incurring more losses is imposed in the form of an increased deductible. In particular, the deductible is increased by the ratio of the maximum cumulative payment (15,000) to the amount that remains available to pay for future losses in the year. The factor by which the deductible can be raised has a limit of three.

This example illustrates only step 3 of the simulation process, where randomization is done. It assumes that step 2 of the simulation process is identical to step 2 of the example in the section “[Illustration of the Aggregate Adjusted Loss Simulation Process](#)” on page 233. At the beginning of step 3, let the severity draws from all the observations be as shown in the `_SEV_` column in the following table:

Obs	age	gender	carType	deductible	count	_sev_		
1	30	2	1	250	2	350	2100	
2	25	1	2	500	1	4500		
3	45	2	2	100	2	700	4300	
4	33	1	1	200	3	600	1500	950
5	50	1	1	200	0			

If the order of these eight draws is not randomized, then all the severity draws for the first observation are adjusted before all the severity draws of the second observation, and so on. The execution of the severity adjustment program leads to the following sequence of values for AmountPaid:

Obs	deductible	_sev_	_adjsevsum_	penaltyFactor	amountPaid
1	250	350	0	1	100
1	250	2100	100	1.0067	1848.32
2	500	4500	1948.32	1.1493	3925.36
3	100	700	5873.68	1.6436	535.64
3	100	4300	6409.32	1.7461	4125.39
4	200	600	10534.72	3	0
4	200	1500	10534.72	3	900
4	200	950	11434.72	3	350

The preceding sequence of simulating loss events results in a cumulative payment of 11,784.72.

If the sequence of draws is randomized over observations, then the computation of the cumulative payment might proceed as follows for one instance of randomization:

Obs	deductible	_sev_	_adjsevsum_	penaltyFactor	amountPaid
2	500	4500	0	1	4000
1	250	350	4000	1.3636	9.09
3	100	700	4009.09	1.3648	563.52
4	200	950	4572.61	1.4385	662.30
4	200	1500	5234.91	1.5361	1192.78
1	250	2100	6427.69	1.7498	1662.54
4	200	600	8090.24	2.1708	165.83
3	100	4300	8256.07	2.2242	4077.58

In this example, a policyholder is identified by the value in the Obs column. As the table indicates, PROC CCDM randomizes the order of loss events not only across policyholders but also across the loss events that a given policyholder incurs. The particular sequence of loss events that is shown in the table results in a cumulative payment of 12,333.65. This differs from the cumulative payment that results from the previously considered nonrandomized sequence of loss events, which tends to penalize the fourth policyholder by always processing her payments after all other payments, with a possibility of underestimating the total amount paid. This comparison not only illustrates that the order of randomization affects the aggregate adjusted loss sample but also corroborates the arguments about the importance of order randomization that are made at the beginning of the section “[Randomizing the Order of Severity Draws across Observations of a Scenario](#)” on page 236.

Parameter Perturbation Analysis

It is important to realize that most of the parameters of the frequency and severity models are estimated and that there is uncertainty associated with the parameter estimates. Any compound distribution estimate that you compute by using these uncertain parameter estimates is inherently uncertain. The aggregate loss sample that you simulate by using the mean estimates of the parameters is just one possible sample from the compound distribution. If information about the uncertainty in parameter estimates is available, then it is recommended that you perform parameter perturbation analysis that generates multiple samples of the compound distribution, in which each sample is simulated by using a set of perturbed parameter estimates. You can use the **NPERTURBEDSAMPLES=** option in the PROC CCDDM statement to specify the number of perturbed samples to be generated. PROC CCDDM creates the set of perturbed parameter estimates by making a random draw of the parameter values from their joint probability distribution. If you specify **NPERTURBEDSAMPLES=P**, then PROC CCDDM creates P sets of perturbed parameters, and each set is used to simulate a full aggregate sample. The summary analysis of P such aggregate loss samples results in a set of P estimates for each summary statistic and percentile of the compound distribution. The mean and standard deviation of this set of P estimates quantify the uncertainty that is associated with the compound distribution.

The parameter estimate uncertainty information is available in the form of either the variance-covariance matrix of the parameter estimates or standard errors of the parameter estimates. If the variance-covariance matrix is available and is positive definite, then PROC CCDDM assumes that the joint probability distribution of the parameter estimates is a multivariate normal distribution, $\mathcal{N}(\boldsymbol{\mu}, \boldsymbol{\Sigma})$, where the mean vector $\boldsymbol{\mu}$ is the set of point parameter estimates and $\boldsymbol{\Sigma}$ is the variance-covariance matrix. If the variance-covariance matrix is not available or is not positive definite, or if you specify the **IGNORECOV** option, then PROC CCDDM assumes that each parameter has a univariate normal distribution, $\mathcal{N}(\mu, \sigma^2)$, where μ is the point estimate of the parameter and σ is the standard error of the parameter estimate.

Specifying Parameter Uncertainty

If you specify the severity models by using the SEVERITYEST= data table, then the point parameter estimates are expected to be available in the SEVERITYEST= data table in observations for which **_TYPE_='EST'**, the standard errors are expected to be available in the SEVERITYEST= data table in observations for which **_TYPE_='STDERR'**, and the variance-covariance matrix is expected to be available in the SEVERITYEST= data table in observations for which **_TYPE_='COV'**. When you use the SEVSELECT procedure to create the SEVERITYEST= data table, you need to specify the COVOUT option in the PROC SEVSELECT statement to make the variance-covariance estimates available in the SEVERITYEST= data table.

If you specify the severity models by using the SEVERITYSTORE= item store, then you need to specify the OUTSTORE= option in the PROC SEVSELECT statement to create that item store, which includes the point parameter estimates and standard errors by default. In addition, you need to specify the COVOUT option in the PROC SEVSELECT statement to make the variance-covariance estimates available in the SEVERITYSTORE= item store.

If you specify the frequency model by using the COUNTSTORE= item store, then the uncertainty estimates are available in that item store, because the CNTSELECT procedure always writes the point estimates, standard errors, and variance-covariance matrix of the parameters to the item store.

If you specify the frequency model by using the **COUNTMODEL** statement, then it is recommended that you use the **STDERROR=** option to specify the standard error for each parameter.

If you specify an external frequency model by using the EXTERNALCOUNTS statement, then there is no way to specify the uncertainty in the frequency model, so PROC CCDM conducts the perturbation analysis by perturbing only the parameters of the severity model.

Output of Perturbation Analysis

PROC CCDM displays the effect of parameter perturbation on the summary statistics and percentiles of the compound distribution in the ODS tables PerturbedSummary and PerturbedPctlSummary, respectively. For each statistic, the tables report the mean and standard error that PROC CCDM computes by aggregating the statistics from all P perturbed samples. For more information, see the section “[Displayed Output](#)” on page 250.

You can specify the OUTSUM statement to write the summary statistics and percentiles of individual perturbed samples to an output data table. You can also specify the PERTURBOUT option in the OUTPUT statement to write all perturbed samples in their entirety to an output data table.

If you specify the ADJUSTEDSEVERITY= option in the PROC CCDM statement, then PROC CCDM performs a separate perturbation analysis for the distribution of each aggregate adjusted loss.

Fixed Parameter-Value Distributions

Table 7.2 and Table 7.3 define the continuous and discrete probability distributions, respectively, that you can use in the SIMULATEDSYMBOL and COUNTMODEL statements. Note the following points when reading both tables:

- You can use any one of the names in the Names column to specify the distribution that the Distribution column identifies. The names are not case-sensitive.
- When you specify the parameter values for a distribution in the COUNTMODEL or SIMULATEDSYMBOL statement, the values must appear in the order in which the parameters are listed in the Parameters column. For example, specifying burr(3, 0.5, 1) means you are specifying $\theta = 3$, $\alpha = 0.5$, and $\gamma = 1$; similarly, specifying negbin(0.3, 5) means you are specifying $p = 0.3$ and $n = 5$.

The following points pertain to the continuous distributions in Table 7.2:

- You can use a continuous distribution in the COUNTMODEL statement only if you use the SIMULATIONMODE= option to specify a simulation mode other than the collective risk mode.
- The definitions of probability density function (PDF) and cumulative distribution functions (CDF) use the following mathematical notation:
 - x denotes the value of the continuous random variable in Table 7.2.
 - $z = x/\theta$, wherever z is used.
 - θ denotes the scale parameter for the continuous distributions.
 - μ denotes the mean parameter, except for the lognormal distribution, where μ is the log-scale parameter ($\mu = \log(\theta)$).
 - $\gamma(a, b) = \int_0^b t^{a-1} e^{-t} dt$ is the lower incomplete gamma function.

– $\Phi(y) = \frac{1}{2} \left(1 + \operatorname{erf} \left(\frac{y}{\sqrt{2}} \right) \right)$ is the standard normal CDF.

- Parameters of the inverse Gaussian (Wald) distribution are related to the parameters of the scaled inverse Gaussian distribution as $\mu = \theta$ and $\lambda = \theta\alpha$.
- The parameters of the Tweedie and scaled Tweedie distribution are related to each other as described in the section “[Tweedie Distributions](#)” on page 1781 in Chapter 26, “[SEVSELECT Procedure](#).” PROC SEVSELECT uses the same parameterizations.
- The parameters of the Wald and scaled Wald distributions are related to each other as $\theta = \mu$ and $\alpha = \lambda/\mu$. PROC SEVSELECT uses the scaled Wald parameterization because it has a scale parameter.

Table 7.2 Fixed Parameter-Value Continuous Distributions

Distribution	Names	Parameters	PDF (f) and CDF (F)
Burr’s Type XII	BurrTypeXII	$\theta > 0$	$f(x) = \frac{\alpha\gamma z^\gamma}{x(1+z^\gamma)^{(\alpha+1)}}$
	Burr	$\alpha > 0$	$F(x) = 1 - \left(\frac{1}{1+z^\gamma} \right)^\alpha$
	Bur	$\gamma > 0$	
Exponential	Exponential	$\theta > 0$	$f(x) = \frac{1}{\theta} e^{-x/\theta}$
	Expo		$F(x) = 1 - e^{-x/\theta}$
	Exp		
Gamma	Gamma	$\theta > 0$	$f(x) = \frac{z^\alpha e^{-z}}{x\Gamma(\alpha)}$
	Gamm	$\alpha > 0$	$F(x) = \frac{\gamma(\alpha, z)}{\Gamma(\alpha)}$
	Gam		
Generalized Pareto	GeneralizedPareto	$\theta > 0$	$f(x) = \frac{1}{\theta} (1 + \xi z)^{-1-1/\xi}$
	GPD	$\xi > 0$	$F(x) = 1 - (1 + \xi z)^{-1/\xi}$
	GPare		
Inverse Gaussian (Wald)	Wald	$\mu > 0$	$f(x) = \sqrt{\frac{\lambda}{2\pi x^3}} e^{-\frac{\lambda(x-\mu)^2}{2\mu^2 x}}$
	IGauss	$\lambda > 0$	$F(x) = \Phi\left(\left(\frac{x}{\mu} - 1\right)\sqrt{\frac{\lambda}{x}}\right) +$
	IGau		$\Phi\left(-\left(\frac{x}{\mu} + 1\right)\sqrt{\frac{\lambda}{x}}\right) e^{2\lambda/\mu}$
Lognormal	Lognormal	μ	$f(x) = \frac{1}{x\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{\log(x)-\mu}{\sigma}\right)^2}$
	Logn	$\sigma > 0$	$F(x) = \Phi\left(\frac{\log(x)-\mu}{\sigma}\right)$
	Lgn		
Normal	Normal	μ	$f(x) = \frac{1}{\sigma\sqrt{2\pi}} e^{-\frac{1}{2}\left(\frac{x-\mu}{\sigma}\right)^2}$
	Gauss	$\sigma > 0$	$F(x) = \Phi\left(\frac{x-\mu}{\sigma}\right)$
	Norm		
Pareto (Type I)	ParetoTypeI	$\theta > 0$	$f(x) = \frac{\alpha}{\theta} \left(\frac{1}{x}\right)^{\alpha+1}$ if $x \geq \theta$; 0 otherwise
	Pareto1	$\alpha > 0$	$F(x) = 1 - \left(\frac{\theta}{x}\right)^\alpha$
	Pare		

Table 7.2 *continued*

Distribution	Names	Parameters	PDF (f) and CDF (F)
Pareto (Type II)	ParetoTypeII	$\theta > 0$	$f(x) = \frac{\alpha\theta^\alpha}{(x+\theta)^{\alpha+1}}$
	Pareto2	$\alpha > 0$	$F(x) = 1 - \left(\frac{\theta}{x+\theta}\right)^\alpha$
	Par2		
Scaled inverse	ScaledWald	$\theta > 0$	$f(x) = \frac{1}{\theta} \sqrt{\frac{\alpha}{2\pi z^3}} e^{-\frac{\alpha(z-1)^2}{2z}}$
Gaussian (Wald)	SWald	$\alpha > 0$	$F(x) = \Phi\left((z-1)\sqrt{\frac{\alpha}{z}}\right) +$
	SIGau		$\Phi\left(-(z+1)\sqrt{\frac{\alpha}{z}}\right) e^{2\alpha}$

	Weib	$\tau > 0$	$F(x) = 1 - e^{-z^\tau}$
	Wbl		

The following points pertain to the discrete distributions in [Table 7.3](#):

- The definition of the probability mass functions (PMF) uses m to denote the value of the discrete random variable. The table does not show an explicit expression for the CDF because the CDF of each distribution is defined in the standard manner as $F(m) = \sum_{i=0}^m f(i)$.
- PROC CCDM supports three parameterizations of the negative binomial distribution to offer flexibility of specification. The standard parameterization (Negbin) is the same as the one you specify in the SAS PDF and CDF functions. The other two are inspired by the parameterizations that the CNTSELECT procedure supports:
 - The NegbinP1 parameterization allows the variance to be linear in mean. NegbinP1(μ, α) is equivalent to Negbin($p = 1/(1 + \alpha)$, $n = \mu/\alpha$).
 - The NegbinP2 parameterization allows the variance to be quadratic in mean. NegbinP2(μ, α) is equivalent to Negbin($p = 1/(1 + \mu\alpha)$, $n = 1/\alpha$).
- The logarithmic versions of the discrete distributions correspond to the distributions that the CNTSELECT procedure uses for the count regression models. The relationship of the parameters of the logarithmic versions and their nonlogarithmic counterparts is as follows:

- $\text{LogCMPoissonLambda}(\beta, \delta) = \text{CMPoisson}(\lambda = e^\beta, \nu = e^{-\delta})$. This distribution corresponds to the parameterization of the Conway-Maxwell-Poisson distribution that PROC CNTSELECT uses when you specify the `DIST=CMPOISSON` and `PARAMETER=LAMBDA` options in the `MODEL` statement of PROC CNTSELECT. The δ parameter corresponds to the `_lnNu` parameter that PROC CNTSELECT reports.
- $\text{LogCMPoissonMu}(\beta, \delta) = \text{CMPoisson}(\lambda = e^{\beta e^{-\delta}}, \nu = e^{-\delta})$. This distribution corresponds to the default parameterization of the Conway-Maxwell-Poisson distribution that PROC CNTSELECT uses, which is equivalent to specifying the `DIST=CMPOISSON` and `PARAMETER=MU` options in the `MODEL` statement of PROC CNTSELECT. The δ parameter corresponds to the `_lnNu` parameter that PROC CNTSELECT reports.
- $\text{LogNegbinP1}(\beta, \alpha) = \text{NegbinP1}(\mu = e^\beta, \alpha)$. This distribution corresponds to the parameterization of the negative binomial distribution that PROC CNTSELECT uses when you specify the `DIST=NEGBIN(P=1)` option in the `MODEL` statement of PROC CNTSELECT.
- $\text{LogNegbinP2}(\beta, \alpha) = \text{NegbinP2}(\mu = e^\beta, \alpha)$. This distribution corresponds to the parameterization of the default negative binomial distribution that PROC CNTSELECT uses when you specify the `DIST=NEGBIN` option in the `MODEL` statement of PROC CNTSELECT.
- $\text{LogPoisson}(\beta) = \text{Poisson}(\lambda = e^\beta)$. This distribution corresponds to the parameterization of the Poisson distribution that PROC CNTSELECT uses when you specify the `DIST=POISSON` option in the `MODEL` statement of PROC CNTSELECT.

Table 7.3 Fixed Parameter-Value Discrete Distributions

Distribution	Names	Parameters	Probability Mass Function (f)
Conway-Maxwell-Poisson (Standard)	CMPOisson	$\lambda > 0$	$f(m) = \frac{\lambda^m}{(m!)^\nu} \frac{1}{Z(\lambda, \nu)}$
	ConMaxPoi CMP	$\nu \geq 0$	where $Z(\lambda, \nu) = \sum_{j=0}^{\infty} \frac{\lambda^j}{(j!)^\nu}$
Log Conway-Maxwell-Poisson (λ -parameterization)	LogCMPoissonLambda	β	$f(m) = \frac{e^{\beta m}}{(m!)^{e^{-\delta}}} \frac{1}{Z(e^\beta, e^{-\delta})}$
	LogCMPL LCMPL	δ	where $Z(e^\beta, e^{-\delta}) = \sum_{j=0}^{\infty} \frac{e^{\beta j}}{(j!)^{e^{-\delta}}}$
Log Conway-Maxwell-Poisson (μ -parameterization)	LogCMPoissonMu	β	$f(m) = \frac{e^{\beta m e^{-\delta}}}{(m!)^{e^{-\delta}}} \frac{1}{Z(e^{\beta e^{-\delta}}, e^{-\delta})}$
	LogCMP LCMP	δ	where $Z(e^{\beta e^{-\delta}}, e^{-\delta}) = \sum_{j=0}^{\infty} \frac{e^{\beta j e^{-\delta}}}{(j!)^{e^{-\delta}}}$
Log negative binomial (variance = $e^\beta + \alpha e^\beta$)	LogNegbinP1	β	$f(m) = \frac{\Gamma(m+\alpha^{-1}e^\beta)}{m!\Gamma(\alpha^{-1}e^\beta)} (1-q)^{\alpha^{-1}e^\beta} q^m$
	LogNB1 LNB1	$\alpha > 0$	where $q = \frac{1}{\alpha^{-1}+1}$
Log negative binomial (variance = $e^\beta + \alpha e^{2\beta}$)	LogNegbinP2	β	$f(m) = \frac{\Gamma(m+\alpha^{-1})}{m!\Gamma(\alpha^{-1})} (1-q)^{\alpha^{-1}} q^m$
	LogNB2 LNB2	$\alpha > 0$	where $q = \frac{e^\beta}{\alpha^{-1}+e^\beta}$

Table 7.3 *continued*

Distribution	Names	Parameters	Probability Mass Function (f)
Log Poisson	LogPoisson LogPoi LPoi	β	$f(m) = e^{-e^\beta} \left(\frac{e^{\beta m}}{m!} \right)$
Negative binomial (standard)	NegativeBinomial Negbin Negb	$0 \leq p \leq 1$ $n > 0$	$f(m) = \binom{n+m-1}{n-1} p^n (1-p)^m$
Negative binomial (variance = $\mu + \alpha\mu$)	NegbinP1 Negb1 NB1	$\mu > 0$ $\alpha > 0$	$f(m) = \frac{\Gamma(m+\alpha^{-1}\mu)}{m!\Gamma(\alpha^{-1}\mu)} (1-q)^{\alpha^{-1}\mu} q^m$ where $q = \frac{1}{\alpha^{-1}+1}$
Negative binomial (variance = $\mu + \alpha\mu^2$)	NegbinP2 Negb2 NB2	$\mu > 0$ $\alpha > 0$	$f(m) = \frac{\Gamma(m+\alpha^{-1})}{m!\Gamma(\alpha^{-1})} (1-q)^{\alpha^{-1}} q^m$ where $q = \frac{\mu}{\alpha^{-1}+\mu}$
Poisson	Poisson Pois Poi	$\lambda > 0$	$f(m) = e^{-\lambda} \frac{\lambda^m}{m!}$

Descriptive Statistics

This section provides computational details for the descriptive statistics that are computed for each aggregate loss sample. You can also save these statistics in an OUTSUM= data table by specifying appropriate keywords in the OUTSUM statement.

This section gives specific details about the moment statistics. For more information about the methods of computing percentile statistics, see the description of the PCTLDEF= option in the UNIVARIATE procedure in the *Base SAS Procedures Guide: Statistical Procedures*.

Standard algorithms (Fisher 1973) are used to compute the moment statistics. The computational methods that the CCDM procedure uses are consistent with those that other SAS procedures use for calculating descriptive statistics.

Mean

The sample mean is calculated as

$$\bar{y} = \frac{\sum_{i=1}^n y_i}{n}$$

where n is the size of the generated aggregate loss sample and y_i is the i th value of the aggregate loss.

Standard Deviation

The standard deviation is calculated as

$$s = \sqrt{\frac{1}{d} \sum_{i=1}^n (y_i - \bar{y})^2}$$

where n is the size of the generated aggregate loss sample, y_i is the i th value of the aggregate loss, $\bar{y}$ is the sample mean, and d is the divisor controlled by the **VARDEF=** option in the PROC CCDDM statement:

$$d = \begin{cases} n - 1 & \text{if VARDEF=DF (default)} \\ n & \text{if VARDEF=N} \end{cases}$$

Skewness

The sample skewness, which measures the tendency of the deviations to be larger in one direction than in the other, is calculated as

$$\frac{1}{d_s} \sum_{i=1}^n \left(\frac{y_i - \bar{y}}{s} \right)^3$$

where n is the size of the generated aggregate loss sample, y_i is the i th value of the aggregate loss, $\bar{y}$ is the sample mean, s is the sample standard deviation, and d_s is the divisor controlled by the **VARDEF=** option in the PROC CCDDM statement:

$$d_s = \begin{cases} \frac{(n-1)(n-2)}{n} & \text{if VARDEF=DF (default)} \\ n & \text{if VARDEF=N} \end{cases}$$

If VARDEF=DF, then n must be greater than 2.

The sample skewness can be positive or negative; it measures the asymmetry of the data distribution and estimates the theoretical skewness $\sqrt{\beta_1} = \mu_3 \mu_2^{-\frac{3}{2}}$, where μ_2 and μ_3 are the second and third central moments. Observations that are normally distributed should have a skewness near zero.

Kurtosis

The sample kurtosis, which measures the heaviness of tails, is calculated as in Table 7.4, depending on the value that you specify in the **VARDEF=** option.

Table 7.4 Formulas for Kurtosis

VARDEF= Value	Formula
DF (default)	$\frac{n(n+1)}{(n-1)(n-2)(n-3)} \sum_{i=1}^n \left(\frac{y_i - \bar{y}}{s} \right)^4 - \frac{3(n-1)^2}{(n-2)(n-3)}$
N	$\frac{1}{n} \sum_{i=1}^n \left(\frac{y_i - \bar{y}}{s} \right)^4 - 3$

In these formulas, n is the size of the generated aggregate loss sample, y_i is the i th value of the aggregate loss, $\bar{y}$ is the sample mean, and s is the sample standard deviation. If VARDEF=DF, then n must be greater than 3.

The sample kurtosis measures the heaviness of the tails of the data distribution. It estimates the adjusted theoretical kurtosis denoted as $\beta_2 - 3$, where $\beta_2 = \frac{\mu_4}{\mu_2^2}$ and μ_4 is the fourth central moment. Observations that are normally distributed should have a kurtosis near zero.

Input Specification

PROC CCDM accepts the COUNTSTORE= item store, DATA= data table, SEVERITYEST= data table, and SEVERITYSTORE= item store as input. This section describes the information that they are expected to contain.

COUNTSTORE= Item Store

The COUNTSTORE= item store is expected to be created by using the STORE= option in the CNTSELECT procedure. You must specify the COUNTSTORE= item store when you do not specify either the COUNTMODEL statement or the EXTERNALCOUNTS statement. For more information, see the description of the STORE= option in the CNTSELECT procedure in *SAS Econometrics: Econometrics Procedures*.

If you specify the BY statement, then the COUNTSTORE= item store must have been created by using a PROC CNTSELECT step that uses an identical BY statement.

DATA= Data Table

If you specify the BY statement, then the DATA= data table must contain all the BY variables that you specify in the BY statement.

If the severity models in the SEVERITYEST= data table or SEVERITYSTORE= item store contain any scale regressors, then all those regressors must be present in the DATA= data table.

If you specify the programming statements to compute an aggregate adjusted loss, and if any of your specified ADJUSTEDSEVERITY= option symbols depend on the severity adjustment variables, then the DATA= data table must contain all such adjustment variables.

The rest of the contents of the DATA= data table depends on whether you specify the EXTERNALCOUNTS statement. If you specify the EXTERNALCOUNTS statement, then the DATA= data table is expected to contain the COUNT= and ID= variables that you specify in the EXTERNALCOUNTS statement. If you specify the COUNTSTORE= item store but you do not specify the EXTERNALCOUNTS statement, then the DATA= data table must contain all the regressors that are present in the count model that the COUNTSTORE= item store contains.

You do not need to specify the DATA= data table if *all* the following conditions are true:

- You do not specify the BY statement.
- You specify the severity models such that none of them are scale regression models.
- You do not specify the EXTERNALCOUNTS statement.

- You specify the COUNTMODEL statement, or you specify a COUNTSTORE= item store such that the count model contains no count regressors.
- Your severity adjustment programming statements, if you specify any, do not use any external input.

If you specify the BY statement, then PROC CCDM analyzes only the BY groups that are present in the input source of the severity models and count models. If neither the severity models nor the count models contain regression effects, then the DATA= data table must contain BY variables and one row for each BY group that you want PROC CCDM to analyze.

SEVERITYEST= Data Table

The SEVERITYEST= data table is expected to contain the parameter estimates of the severity models. This is a required data table; you must specify it whenever you use PROC CCDM.

The SEVERITYEST= data table must be an OUTEST= data table that the SEVSELECT procedure creates. For more information, see the description of the OUTEST= data table in the SEVSELECT procedure in *SAS Econometrics: Econometrics Procedures*.

If you specify the BY statement, then the SEVERITYEST= data table must contain all the BY variables that you specify in the BY statement.

SEVERITYSTORE= Item Store

The SEVERITYSTORE= item store is expected to be created by using the OUTSTORE= option in a PROC SEVSELECT statement. For more information, see the description of the OUTSTORE= option in the SEVSELECT procedure in *SAS Econometrics: Econometrics Procedures*.

You must specify this item store when you do not specify the SEVERITYEST= data table. Also, if your severity model is a scale regression model that contains classification or interaction effects, then you cannot use the SEVERITYEST= data table. You must specify such severity models by specifying the SEVERITYSTORE= item store.

If you specify the BY statement, then the SEVERITYSTORE= item store must have been created by using a PROC SEVSELECT step that uses an identical BY statement.

Output Data Tables

PROC CCDM writes the output data tables that you specify in the OUT= option of the OUTPUT and OUTSUM statements. It also produces an output data table of individual severity draws when you specify the OUTDRAW= option. The contents of these output data tables are described in the following sections.

OUTDRAW= Data Table

The OUTDRAW= data table records the individual severity draws.

If you specify the BY statement, then the data table contains variables that you specify in the BY statement. In addition, the OUTDRAW= data table contains the following variables:

`_SEVERITYMODEL_`

indicates the name of the severity distribution model.

`_COUNTMODEL_`

indicates the name of the count model. If you specify the `EXTERNALCOUNTS` statement, then the value of this variable is “`_EXTERNAL_`”.

`_DRAWID_`

indicates the identifier for the perturbed sample. This variable is created only when you specify the `NPERTURBEDSAMPLES=` option in the `PROC CCDM` statement. The value of this variable identifies the perturbed sample. A value of 0 indicates an unperturbed sample.

`_BEGINAGG_`

indicates whether the observation starts a new aggregate sample point or continues the previous aggregate sample point. A value of 1 indicates that a new aggregate sample point begins. A value of 0 indicates that the observation continues the aggregate sample point.

`_SEVERITYDRAW_`

indicates the value of the severity draw.

OUTSAMPLE= Data Table

The `OUTSAMPLE=` data table records the full sample of the aggregate loss and aggregate adjusted loss.

If you specify the `BY` statement, then the data table contains variables that you specify in the `BY` statement. In addition, the `OUTSAMPLE=` data table contains the following variables:

`_SEVERITYMODEL_`

indicates the name of the severity distribution model.

`_COUNTMODEL_`

indicates the name of the count model. If you specify the `EXTERNALCOUNTS` statement, then the value of this variable is “`_EXTERNAL_`”.

`<sample variable>`

indicates the value of the aggregate unadjusted loss. The name of this variable is the value of the `SAMPLEVAR=` option in the `OUTPUT` statement. If you do not specify the `SAMPLEVAR=` option, then this variable is named `_AGGSEV_`.

`<adjusted sample variable 1> ... <adjusted sample variable D>`

indicates the values of the D aggregate adjusted losses, where D is the number of adjusted severity symbols that you specify in the `ADJUSTEDSEVERITY=` option in the `PROC CCDM` statement. The names of these variables are the values of the `ADJSAMPLEVAR=` option in the `OUTPUT` statement, which are applied to the symbols in the order in which you specify them in the `ADJUSTEDSEVERITY=` option. If you specify fewer names in the `ADJSAMPLEVAR=` option than symbols in the `ADJUSTEDSEVERITY=` option, then the variable for each remaining adjusted severity symbol has the same name as the corresponding symbol. If you do not specify the `ADJSAMPLEVAR=` option in the `OUTPUT` statement, if you specify only one adjusted severity symbol in the `ADJUSTEDSEVERITY=` option, and if you specify the `ONEADJSEVCOMPAT` option, then the adjusted sample variable is named `_AGGADJSEV_`.

DRAWID indicates the identifier for the perturbed sample. This variable is created only when you specify the **NPERTURBEDSAMPLES=** option in the PROC CCDM statement and the **PERTURBOUT** option in the OUTPUT statement. The value of this variable identifies the perturbed sample. A value of 0 indicates an unperturbed sample.

Observations that have the same **_DRAWID_** variable value are always distributed across all worker nodes for the unperturbed sample (**_DRAWID_** = 0). For each of the perturbed samples (**_DRAWID_** > 0), observations are either distributed or partitioned across worker nodes, depending on the value of the **PERTURBMODE=** option. For more information, see the description of the **PERTURBMODE=AUTO** option.

OUTSUM= Data Table

The OUTSUM= data table records the summary statistics and percentiles of the compound distributions of aggregate loss and aggregate adjusted loss. Only the estimates that you request in the OUTSUM statement are written to the OUTSUM= data table. For more information about the method of naming the variables that correspond to the summary statistics or percentiles, see the description of the **OUTSUM** statement.

If you specify the BY statement, then the data table contains variables that you specify in the BY statement. In addition, the OUTSUM= data table contains the following variables:

SEVERITYMODEL indicates the name of the severity distribution model.

COUNTMODEL indicates the name of the count model. If you specify the **EXTERNALCOUNTS** statement, then the value of this variable is “**_EXTERNAL_**”.

SAMPLEVAR indicates the name of the aggregate loss sample. For an unadjusted sample, the value of the variable is the value of the **SAMPLEVAR=** option that you specify in the OUTPUT statement. If you do not specify the **SAMPLEVAR=** option, then the default value is **_AGGSEV_**.

For an adjusted sample, the value of the variable is decided by the value of the **ADJSAMPLEVAR=** option that you specify in the OUTPUT statement or the name of the adjusted severity symbol. If you do not specify the **ADJSAMPLEVAR=** option, if you specify only one adjusted severity symbol in the **ADJUSTEDSEVERITY=** option, and if you specify the **ONEADJSEVCOMPAT** option, then the value is **_AGGADJSEV_**.

DRAWID indicates the identifier for the perturbed sample. This variable is created only when you specify the **NPERTURBEDSAMPLES=** option in the PROC CCDM statement. The value of this variable identifies the perturbed sample. A value of 0 indicates an unperturbed sample.

Displayed Output

The CCDM procedure optionally produces displayed output by using the Output Delivery System (ODS). You control all output by using the PRINT= option in the PROC CCDM statement. Table 7.5 relates the PRINT= options to ODS tables.

Table 7.5 ODS Tables Produced in PROC CCDM

ODS Table Name	Description	Option
CompoundInfo	Compound distribution information	Default
DataSummary	Input data summary	Default
Percentiles	Percentiles of the aggregate loss sample	PRINT=PERCENTILES
PerturbedPctlSummary	Perturbation analysis of percentiles	PRINT=PERTURBSUMMARY and NPerturbedSamples > 0
PerturbedSummary	Perturbation analysis of summary statistics	PRINT=PERTURBSUMMARY and NPerturbedSamples > 0
SummaryStatistics	Summary statistics of the aggregate loss sample	PRINT=SUMMARYSTATISTICS
Timing	Timing information for various computational stages of the procedure	PRINT=ALL

PRINT= Option

This section provides detailed descriptions of the tables that you display by using different PRINT= options.

- If you do not specify the PRINT= option and if you do not specify the NOPRINT or PRINT=NONE options, then by default PROC CCDM produces the CompoundInfo, DataSummary, and SummaryStatistics ODS tables.

The “Compound Distribution Information” table (ODS name CompoundInfo) displays the information about the severity and count models.

The “Input Data Summary” table (ODS name DataSummary) is displayed when you specify the DATA= data table. The table displays the total number of observations and the valid number of observations in the data table. If you specify the EXTERNALCOUNTS statement, then the table also displays the number of replications and total number of loss events across all replications.

- If you specify PRINT=PERCENTILES, the “Percentiles” table (ODS name Percentiles) is displayed for the distribution of the aggregate loss. The table contains estimates of all predefined percentiles in addition to the percentiles that you request in the OUTSUM statement.

If you specify the programming statements and the ADJUSTEDSEVERITY= option symbols, then an additional table is displayed for the distribution of each aggregate adjusted loss. These tables also contain estimates of all predefined percentiles in addition to the percentiles that you request in the OUTSUM statement.

- If you specify `PRINT=PERTURBSUMMARY`, two tables are displayed for the distribution of the aggregate loss. The “Perturbed Summary Statistics” table (ODS name `PerturbedSummary`) displays the summary of the effect of perturbing model parameters on the following five summary statistics of the distribution: mean, standard deviation, variance, skewness, and kurtosis. The “Perturbed Percentiles” table (ODS name `PerturbedPctlSummary`) displays the perturbation summary for all predefined percentiles in addition to the percentiles that you request in the `OUTSUM` statement.

The tables are displayed only if you specify a value greater than 0 for the `NPERTURBEDSAMPLES=` option.

If you specify a value of P for the `NPERTURBEDSAMPLES=` option, then for each summary statistic and percentile, an average and standard error of the set of P values of that summary statistic or percentile are displayed in the respective perturbation summary tables.

If you specify the programming statements and the `ADJUSTEDSEVERITY=` option symbols, then additional perturbation summary tables are displayed for the distribution of each aggregate adjusted loss.

- If you specify `PRINT=SUMMARYSTATISTICS`, the “Summary Statistics” table (ODS name `SummaryStatistics`) is displayed for the distribution of the aggregate loss. The table contains estimates of the following summary statistics: number of observations in the sample, maximum value in the sample, minimum value in the sample, mean, median, standard deviation, interquartile range, variance, skewness, and kurtosis.

If you specify the programming statements and the `ADJUSTEDSEVERITY=` option symbols, then an additional table of summary statistics is displayed for the distribution of each aggregate adjusted loss.

ODS Graphics

This section describes the use of ODS for creating graphics with the CCDM procedure.

NOTE: To create the plots, PROC CCDM prepares a plot data table that contains an estimate of the empirical distribution function (EDF) for a carefully selected subsample of the simulated aggregate loss sample and brings that table back to the client machine where your SAS session is running. You can control the size of the plot data table by specifying the `NOBS=` and `NADJSEVTOPILOT=` options. The larger the size of this table, the more accurate are the plots, but the more expensive it is to prepare and display the plots. So it is recommended that you request plots only when the full aggregate loss sample is not too large and that you do not specify large values for the `NOBS=` and `NADJSEVTOPILOT=` options.

ODS Graph Names

PROC CCDM assigns a name to each graph that it creates by using ODS. You can use these names to selectively refer to the graphs. The names are listed in [Table 7.6](#).

Table 7.6 ODS Graphics Produced by PROC CCDDM

ODS Graph Name	Plot Description	PLOTS= Option
ConditionalDensityPlot	Conditional density plot	CONDITIONALDENSITY
DensityPlot	Probability density function plot	DENSITY
EDFPlot	Empirical distribution function plot	EDF

Conditional Density Plot

The conditional density plot helps you visually analyze two or three regions of the compound distribution by displaying a density function estimate that is conditional on the values of the aggregate loss that fall in those regions. You can specify the region boundaries in terms of quantiles by using the **LEFTQ=** and **RIGHTQ=** suboptions of the **PLOTS=CONDITIONALDENSITY** option. This is especially useful if you want to see the distribution of aggregate loss values in the right- and left-tail regions.

If you specify m symbols in the **ADJUSTEDSEVERITY=** option and if you specify **NADJSEVTOPLOT= k** in the **PLOTS=** option, then separate sets of conditional density plots are displayed for the first l aggregate adjusted loss samples, where $l = \min(k, m)$.

Probability Density Function Plot

The probability density function (PDF) plot shows the nonparametric estimates of the PDF of the aggregate loss distribution. This plot includes histogram and kernel density estimates.

If you specify m symbols in the **ADJUSTEDSEVERITY=** option and if you specify **NADJSEVTOPLOT= k** in the **PLOTS=** option, then separate density plots are displayed for the first l aggregate adjusted loss samples, where $l = \min(k, m)$.

Empirical Distribution Function Plot

The empirical density function (EDF) plot shows the nonparametric estimate of the cumulative distribution function of the aggregate loss distribution. You can specify the **ALPHA=** suboption of the **PLOTS=EDF** option to request that the upper and lower confidence limits be plotted for each EDF estimate. By default, the confidence interval is not plotted.

If you specify m symbols in the **ADJUSTEDSEVERITY=** option and if you specify **NADJSEVTOPLOT= k** in the **PLOTS=** option, then separate EDF plots are displayed for the first l aggregate adjusted loss samples, where $l = \min(k, m)$.

Examples: CCDM Procedure

Example 7.1: Estimating the Probability Distribution of Insurance Payments

The primary outcome of running the CCDM procedure is the estimate of the compound distribution of aggregate loss, given the distributions of frequency and severity of the individual losses. This aggregate loss is often referred to as the ground-up loss. If you are an insurance company or a bank, you are also interested in acting on the ground-up loss by computing an entity that is derived from the ground-up loss. For example, you might want to estimate the distribution of the amount that you are expected to pay for the losses or the distribution of the amount that you can offload to another organization, such as a reinsurance company. PROC CCDM enables you to specify a severity adjustment program, which is a sequence of SAS programming statements that adjust the severity of the individual loss event to compute the entity of interest. Your severity adjustment program can use external information that is recorded as variables in the observations of the DATA= data table in addition to placeholder symbols for information that PROC CCDM generates internally, such as the severity of the current loss event (`_SEV_`) and the sum of the adjusted severity values of the events that have been simulated thus far for the current sample point (`_ADJSEVSUM_`). If you are analyzing a scenario that contains more than one observation, then you can also access the cumulative severity and cumulative adjusted severity for the current observation by using the `_SEVSUMFOROBS_` and `_ADJSEVSUMFOROBS_` symbols.

This example continues the example of the section “[Scenario Analysis](#)” on page 183 to illustrate how you can estimate the distribution of the aggregate amount that is paid to a group of policyholders. Let the amount that is paid to an individual policyholder be computed by using what is usually referred to as a *disappearing deductible* (Klugman, Panjer, and Willmot 1998, Ch. 2). If X denotes the ground-up loss that a policyholder incurs, d denotes the lower limit on the deductible, d' denotes the upper limit on the deductible, and u denotes the limit on the total payments that are made to a policyholder in a year, then Y , the amount that is paid to the policyholder for each loss event, is defined as follows:

$$Y = \begin{cases} 0 & X \leq d \\ d' \frac{X-d}{d'-d} & d < X \leq d' \\ X & d' < X \leq u \\ u & X > u \end{cases}$$

You can use a set of SAS programming statements to encode this logic.

The following DATA step extends the data table `mylib.GroupOfPolicies` from the example in the section “[Scenario Analysis](#)” on page 183 to include three additional variables for each policyholder: `LowDeductible` to record d , `HighDeductible` to record d' , and `Limit` to record u .

```
/* Generate the scenario data table for multiple policyholders */
data groupOfPolicies(keep=policyholderId age gender carType annualMiles
                    education carSafety income
                    lowDeductible highDeductible limit annualLimit);
  call streaminit(67897);

  do policyholderId=1 to 5;
    age = MAX(int(rand('NORMAL', 35, 15)),16)/50;
```

```

if (rand('UNIFORM') < 0.5) then gender = 1; * female;
else gender = 2; * male;

if (rand('UNIFORM') < 0.7) then carType = 1; * sedan;
else carType = 2; * SUV;

annualMiles = MAX(1000, int(rand('NORMAL', 12000, 5000)))/5000;

educationLevel = rand('UNIFORM');
if (educationLevel < 0.5) then education = 1; *high school graduate;
else if (educationLevel < 0.85) then education = 2; *college graduate;
else education = 3; *advanced degree;

carSafety = rand('UNIFORM'); /* scaled to be between 0 & 1 */

income = MAX(15000,int(rand('NORMAL', education*30000, 50000)))/100000;

lowDeductible = 100*(1+floor(rand('UNIFORM')*5));
highDeductible = lowDeductible + 500*(1+floor(rand('UNIFORM')*2));
limit = 2500*(1+floor(rand('UNIFORM')*3));
annualLimit = 10000*(1+floor(rand('UNIFORM')*2));

output;
end;
run;

/* Load the data */
data mylib.groupOfPolicies;
  set groupOfPolicies;
run;

```

The data table contains the observations as shown in [Output 7.1.1](#).

Output 7.1.1 Scenario Analysis Data for Multiple Policyholders with Policy Provisions

policyholderId	age	gender	carType	annualMiles	education	carSafety	income

5	0.44	1	1	0.9670	2	0.08656	0.65979

lowDeductible	highDeductible	limit	annualLimit
400	1400	7500	10000
300	1300	2500	20000
100	1100	5000	10000
300	800	5000	20000
100	1100	5000	20000

The following PROC CCDM step estimates the compound distributions of the aggregate loss and the aggregate amount that is paid to the group of policyholders in the data table mylib.GroupOfPolicies by using the count model that is stored in the item store mylib.CountregModel and the lognormal severity model that is

stored in the data table mylib.SevRegEst:

```
/* Simulate the aggregate loss distribution and aggregate adjusted
   loss distribution for the scenario of multiple policyholders */
proc ccdm data=mylib.groupOfPolicies nreplicates=10000 seed=13579 print=all
      countstore=mylib.countregmodel severityest=mylib.sevregest
      nperturbedSamples=50 adjustedseverity=amountPaid;
      severitymodel logn;

      if (_sev_ <= lowDeductible) then
        amountPaid = 0;
      else do;
        if (_sev_ <= highDeductible) then
          amountPaid = highDeductible *
            (_sev_-lowDeductible)/(highDeductible-lowDeductible);
        else
          amountPaid = MIN(_sev_, limit); /* imposes per-loss payment limit */
        end;
      run;
```

The preceding step uses a severity adjustment program to compute the value of the symbol AmountPaid and specifies that symbol in the ADJUSTEDSEVERITY= option in the PROC CCDM step. The program is executed for each simulated loss event. The PROC CCDM supplies your program with the value of the severity in the _SEV_ placeholder symbol.

The “Sample Summary Statistics” table in [Output 7.1.2](#) shows the summary statistics of the compound distribution of the aggregate ground-up loss. The “Adjusted Sample Summary Statistics” table shows the summary statistics of the compound distribution of the aggregate AmountPaid.

Output 7.1.2 Summary Statistics of Compound Distributions of the Total Loss and Total Amount Paid

The CCDM Procedure

The perturbation summary of the distribution of AmountPaid is shown in [Output 7.1.3](#). It shows that you can expect to pay a median amount to this group of five policyholders in a year.

Output 7.1.3 Perturbation Summary of the Total Amount Paid

Percentile Perturbation Analysis for amountPaid			
Percentile	Estimate	Standard Error	
1	0.35077	2.45538	
5	391.31471	57.78032	
25	1988.2	164.12121	
50	3781.8	247.83745	
75	6131.5	344.12552	
95	10433.8	508.50465	
99	14094.6	663.38390	
99.5	15570.8	727.38674	
Number of Perturbed Samples = 50			
Size of Each Sample = 10000			

Now consider that, in the future, you want to modify your company's policy provisions to add a limit on the total amount of payment that an individual policyholder receives in one year and to impose a group limit of 15,000 on the total amount of payments the group as a whole receives in one year. You can analyze the effects of these modified policy provisions on the distribution of the aggregate paid amount by recording the individual policyholder's annual limit in the variable AnnualLimit of the input data table and then modifying your severity adjustment program by using the placeholder symbols `_ADJSEVSUMFOROBS_` and `_ADJSEVSUM_`, as in the following PROC CCDM step:

```
/* Simulate the aggregate loss distribution and aggregate adjusted
   loss distribution for the modified set of policy provisions */
proc ccdm data=mylib.groupOfPolicies nreplicates=10000 seed=13579 print=all
      countstore=mylib.countregmodel severityest=mylib.sevregest
      nperturbedSamples=50 adjustedseverity=amountPaid;
severitymodel logn;

if (_sev_ <= lowDeductible) then
  amountPaid = 0;
```

```

else do;
  if (_sev_ <= highDeductible) then
    amountPaid = highDeductible *
      (_sev_-lowDeductible)/(highDeductible-lowDeductible);
  else
    amountPaid = MIN(_sev_, limit); /* imposes per-loss payment limit */

  /* impose policyholder's annual limit */
  amountPaid = MIN(amountPaid, MAX(0,annualLimit - _adjsevsumforobs_));

  /* impose group's annual limit */
  amountPaid = MIN(amountPaid, MAX(0,15000 - _adjsevsum_));
end;
run;

```

The results of the perturbation analysis for these modified policy provisions are shown in [Output 7.1.4](#). When you compare them to the results in [Output 7.1.3](#), you see that the additional policy provisions of restricting the total payment to the policyholder and the group have reduced the median payment and the worst-case payment (99.5th percentile).

Output 7.1.4 Perturbation Summary of the Total Amount Paid after Modified Policy Provisions

Example 7.2: Using Externally Simulated Count Data

The COUNTREG procedure in SAS/ETS and the CNTSELECT procedure in SAS Econometrics enable you to estimate count regression models that are based on the most commonly used discrete distributions, such as the Poisson, negative binomial (both $p = 1$ and $p = 2$), and Conway-Maxwell-Poisson distributions. Those procedures also enable you to fit zero-inflated models that are based on Poisson, negative binomial ($p = 2$), and Conway-Maxwell-Poisson distributions. However, you might encounter situations in which you want to use a different method of fitting count regression models. For example, if you are modeling the number of loss events that are incurred by two financial instruments such that there is some dependency between the two, then you might use multivariate frequency modeling methods and simulate the counts for each instrument by using the dependency structure between the count model parameters of the two instruments. As another example, you might want to use different types of count models for different BY groups in your data; this is not possible in PROC COUNTREG or PROC CNTSELECT. So you need to simulate the counts for such BY groups externally. The CCDM procedure enables you to supply externally simulated counts by using the EXTERNALCOUNTS statement. PROC CCDM then does not need to simulate the counts internally; it simulates only the severity of each loss event by using the severity model estimates that you specify in the SEVERITYEST= data table or the SEVERITYSTORE= item store. The simulation process is described and illustrated in the section “[Simulation with External Counts](#)” on page 221.

Consider that you are a bank, and as part of quantifying your operational risk, you want to estimate the aggregate loss distributions for two lines of business, retail banking and commercial banking, by using some key risk indicators (KRIs). Assume that your model fitting and model selection process has determined that the Poisson regression model and negative binomial regression model are the best-fitting count models for the number of loss events that are incurred in the retail banking and commercial banking lines, respectively. Let CorpKRI1, CorpKRI2, CbKRI1, CbKRI2, and CbKRI3 be the KRIs that you use in the count regression model of the commercial banking line, and let CorpKRI1, RbKRI1, and RbKRI2 be the KRIs that you use in the count regression model of the retail banking line. Examples of corporate-level KRIs (CorpKRI1 and CorpKRI2 in this example) are the ratio of temporary to permanent employees and the number of security breaches that are reported during a year. Examples of KRIs that are specific to the commercial banking business (CbKRI1, CbKRI2, and CbKRI3 in this example) are number of credit defaults, proportion of financed assets that are movable, and penalty claims against your bank because of processing delays. Examples of KRIs that are specific to the retail banking business (RbKRI1 and RbKRI2 in this example) are number of credit cards that are reported stolen, fraction of employees who have not undergone fraud detection training, and number of forged drafts and checks that are presented in a year.

Let the severity of each loss event in the commercial banking business be dependent on two KRIs, CorpKRI1 and CbKRI2. Let the severity of each loss event in the retail banking business be dependent on three KRIs, CorpKRI2, RbKRI1, and RbKRI3. Note that for each line of business, the set of KRIs that are used for the severity model is different from the set of KRIs that are used for the count model, although the two sets overlap. Further, the severity model for retail banking includes a new regressor (RbKRI3) that is not used for any of the count models. Such use of different sets of KRIs for count and severity models is typical of real-world applications.

Let the parameter estimates of the negative binomial and Poisson regression models be available in the data sets Work.CountEstEx2NB2 and Work.CountEstEx2Poisson, respectively. The following statements produce them by using the OUTEST= option in the respective PROC COUNTREG statements:

```

/* Simulate count data */
data cntdataex2(keep=line corpKRI1 corpKRI2
                cbKRI1 cbKRI2 cbKRI3 rbKRI1 rbKRI2 numloss);
  call streaminit(12345);
  array cx{7} corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3 rbKRI1 rbKRI2;
  array cbetaR{8} _TEMPORARY_ (0.35 1 0 0 0 0 0.5 0.25);
  array cbetaC{8} _TEMPORARY_ (0.9 0.75 0.3 0.1 0.25 0.5 0 0);

  alpha = 0.3;
  theta = 1/alpha;
  do obs=1 to 5000;
    do i=1 to dim(cx);
      cx(i) = rand('NORMAL');
    end;

    line = 'CommercialBanking';
    xbeta = cbetaC(1);
    do i=1 to dim(cx);
      xbeta = xbeta + cx(i) * cbetaC(i+1);
    end;
    Mu = exp(xbeta);
    p = theta/(Mu+theta);
    numloss = rand('NEGB',p,theta);
    output;

    line = 'RetailBanking';
    xbeta = cbetaR(1);
    do i=1 to dim(cx);
      xbeta = xbeta + cx(i) * cbetaR(i+1);
    end;
    lambda = exp(xbeta);
    numloss = rand('POISSON', lambda);
    output;
  end;
run;

proc sort data=cntdataex2;
  by line;
run;

/* Fit negative binomial (p=2) regression model for each business line */
proc countreg data=cntdataex2 outest=countEstEx2NB2;
  by line;
  model numloss = corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3
                rbKRI1 rbKRI2 / dist=negbin;
run;

/* Fit Poisson regression model for each business line */
proc countreg data=cntdataex2 outest=countEstEx2Poisson;
  by line;
  model numloss = corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3
                rbKRI1 rbKRI2 / dist=poisson;
run;

```

NOTE: PROC CNTSELECT does not support the OUTEST= option, so unlike other examples that use PROC CNTSELECT to estimate count models, the preceding statements use PROC COUNTREG.

Let the parameter estimates of the best-fitting severity models, as determined by PROC SEVSELECT, be available in the data table mylib.SevEstEx2, as prepared by the following statements:

```
/* Simulate severity data */
data sevdataEx2(keep=line corpKRI1 corpKRI2 cbKRI2 rbKRI1 rbKRI3 lossValue);
  array sx{5} corpKRI1 corpKRI2 cbKRI2 rbKRI1 rbKRI3;
  array sbetaC{6} _TEMPORARY_ (5 1 0 0.3 0 0);
  array sbetaR{6} _TEMPORARY_ (3.5 0 0.5 0 -0.8 0.6);
  if (_n_=1) then call streaminit(67890);

  set cntdataex2(keep=line numloss corpKRI1 corpKRI2 cbKRI2 rbKRI1);
  sigma = 1;
  alpha = 2.5;
  if (numloss > 0) then do;
    sx(5) = rand('NORMAL'); /* simulate rbKRI3 value */

    if (line='CommercialBanking') then do;
      /* lognormal */
      Mu = sbetaC(1);
      do i=1 to dim(sx);
        Mu = Mu + sx(i) * sbetaC(i+1);
      end;
      lossValue = exp(Mu) * rand('LOGNORMAL')**Sigma;
    end;
  else do;
    /* gamma */
    Mu = sbetaR(1);
    do i=1 to dim(sx);
      Mu = Mu + sx(i) * sbetaR(i+1);
    end;
    lossValue = quantile('Gamma', rand('UNIFORM'), Alpha, exp(Mu));
  end;
  output;
end;
run;

/* Load the data */
data mylib.sevdataEx2;
  set sevdataEx2;
run;

/* Fit severity models for each business line */
proc sevselect data=mylib.sevdataEx2 outest=mylib.sevestEx2;
  by line;
  loss lossValue;
  scalemodel corpKRI1 corpKRI2 cbKRI2 rbKRI1 rbKRI3;
  dist logn gamma;
run;
```

Now, consider that you want to estimate the distribution of the aggregate loss for a scenario, which is represented by a specific set of KRI values. The following DATA step illustrates one such scenario:

```

/* Generate a scenario data table for a single operating condition */
data singleScenario (keep=corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3
                    rbKRI1 rbKRI2 rbKRI3);
    array x{8} corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3 rbKRI1 rbKRI2 rbKRI3;
    call streaminit(5151);
    do i=1 to dim(x);
        x(i) = rand('NORMAL');
    end;
    output;
run;

/* Load the data */
data mylib.singleScenario;
    set singleScenario;
run;

```

The data table mylib.SingleScenario contains all the KRIs that are included in the count and severity models of both business lines. Note that if you standardize or scale the KRIs while fitting the count and severity models, then you must apply the same standardization or scaling method to the values of the KRIs that you specify in the scenario. In this particular example, all KRIs are assumed to be standardized.

The following DATA step uses the scenario in the data table mylib.SingleScenario to simulate 10,000 replications of the number of loss events that you might observe for each business line and writes the simulated counts to the variable NumLoss of the data table mylib.LossCounts1:

```

/* Simulate multiple replications of the number of loss events that
   you can expect in the scenario being analyzed */
data lossCounts1 (keep=line corpKRI1 corpKRI2 cbKRI2 rbKRI1 rbKRI3 numloss);
    array cxR{3} corpKRI1 rbKRI1 rbKRI2;
    array cbetaR{4} _TEMPORARY_;
    array cxC{5} corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3;
    array cbetaC{6} _TEMPORARY_;

    retain theta;
    if _n_ = 1 then do;
        call streaminit(5151);
        /* read count model estimates */
        set countEstEx2NB2(where=(line='CommercialBanking' and _type_='PARM'));
        cbetaC(1) = Intercept;
        do i=1 to dim(cxC);
            cbetaC(i+1) = cxC(i);
        end;
        alpha = _Alpha;
        theta = 1/alpha;

        set countEstEx2Poisson(where=(line='RetailBanking' and _type_='PARM'));
        cbetaR(1) = Intercept;
        do i=1 to dim(cxR);
            cbetaR(i+1) = cxR(i);
        end;
    end;

    set singleScenario;

```

```

do iline=1 to 2;
  if (iline=1) then line = 'CommercialBanking';
  else line = 'RetailBanking';
  do repid=1 to 10000;
    /* draw from count distribution */
    if (iline=1) then do;
      xbeta = cbetaC(1);
      do i=1 to dim(cxC);
        xbeta = xbeta + cxC(i) * cbetaC(i+1);
      end;
      Mu = exp(xbeta);
      p = theta/(Mu+theta);
      numloss = rand('NEGB',p,theta);
    end;
    else do;
      xbeta = cbetaR(1);
      do i=1 to dim(cxR);
        xbeta = xbeta + cxR(i) * cbetaR(i+1);
      end;
      numloss = rand('POISSON', exp(xbeta));
    end;
    output;
  end;
end;
run;

/* Load the data */
data mylib.lossCounts1;
  set lossCounts1;
run;

```

The mylib.LossCounts1 data table contains the variable NumLoss in addition to the KRIs that the severity regression model uses, which PROC CCDM needs in order to simulate the aggregate loss.

Now, you are ready to estimate the aggregate loss distribution for each line of business by submitting the following PROC CCDM step, in which you specify the EXTERNALCOUNTS statement to request that external counts in the variable NumLoss of the DATA= data table be used for simulation of the aggregate loss:

```

/* Estimate the distribution of the aggregate loss for both
   lines of business by using the externally simulated counts */
proc ccdm data=mylib.lossCounts1 seed=13579 print=all
  severityest=mylib.sevestEx2;
  by line;
  externalcounts count=numloss;
  severitymodel logn gamma;
run;

```

Each observation in the mylib.LossCounts1 data table represents one replication of the external counts simulation process. For each such replication, the preceding PROC CCDM step makes as many severity draws from the severity distribution as the value of the NumLoss variable, and it adds together the severity values from those draws to compute one sample point of the aggregate loss. The severity distribution that is used for making the severity draws has a scale parameter value that is determined by the KRI values in the given observation and by the regression parameter values that are read from the mylib.SevEstEx2 data table.

The summary statistics and percentiles of the aggregate loss distribution for the commercial banking business, which uses the lognormal severity model, are shown in [Output 7.2.1](#). The “Input Data Summary” table indicates that each of the 10,000 observations in the BY group is treated as one replication and that a total of 19,028 loss events were produced by all the replications together. For the scenario in the data table mylib.SingleScenario, the commercial banking line incurs an average aggregate loss as shown in the “Sample Summary Statistics” table, and the chance that the loss will exceed the 99.5th percentile is about 0.5%, as shown in the “Sample Percentiles” table.

Output 7.2.1 Aggregate Loss Summary for Commercial Banking Line

The CCDM Procedure

When you conduct simulation and estimation for a scenario that contains only one observation, you assume that the operating environment does not change over the period of time that is being analyzed. That assumption might be valid for shorter durations and stable business environments, but often the operating environments change, especially if you are estimating the aggregate loss over a longer period of time. So you might want to include in your scenario all the possible operating environments that you expect to see during the analysis time period. Each environment is characterized by its own set of KRI values. For example, the operating conditions might change from quarter to quarter, and you might want to estimate the aggregate loss distribution for the entire year. You start the estimation process for such scenarios by creating a scenario data table. The following DATA step creates the data table `mylib.MultiConditionScenario`, which consists of four operating environments, one for each quarter:

```
/* Generate a scenario data table for multiple operating conditions */
data multiConditionScenario (keep=opEnvId corpKRI1 corpKRI2
    cbKRI1 cbKRI2 cbKRI3 rbKRI1 rbKRI2 rbKRI3);
    array x{8} corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3 rbKRI1 rbKRI2 rbKRI3;
    call streaminit(5151);
    do opEnvId=1 to 4;
        do i=1 to dim(x);
            x(i) = rand('NORMAL');
        end;
        output;
    end;
run;

/* Load the data */
data mylib.multiConditionScenario;
    set multiConditionScenario;
run;
```

All four observations of the data table `mylib.MultiConditionScenario` together form one scenario. When you simulate the external counts for such multi-entity scenarios, one replication consists of the possible number of loss events that can occur as a result of all four operating environments. In any given replication, some operating environments might not produce any loss event, or all four operating environments might produce some loss events. The following DATA step creates the data table `mylib.LossCounts2`, which contains, for each business line, 10,000 replications of the loss counts, and which identifies each replication by using the

variable RepId:

```

/* Simulate multiple replications of the number of loss events that you can
   expect for all operating environments in the scenario being analyzed */
data lossCounts2 (keep=line opEnvId corpKRI1 corpKRI2 cbKRI2
                  rbKRI1 rbKRI3 repid numloss);
array cxR{3} corpKRI1 rbKRI1 rbKRI2;
array cbetaR{4} _TEMPORARY_;
array cxC{5} corpKRI1 corpKRI2 cbKRI1 cbKRI2 cbKRI3;
array cbetaC{6} _TEMPORARY_;

/* Read the count model estimates */
retain theta;
if _n_ = 1 then do;
  call streaminit(5151);
  set countEstEx2NB2(where=(line='CommercialBanking' and _type_='PARM'));
  cbetaC(1) = Intercept;
  do i=1 to dim(cxC);
    cbetaC(i+1) = cxC(i);
  end;
  alpha = _Alpha;
  theta = 1/alpha;

  set countEstEx2Poisson(where=(line='RetailBanking' and _type_='PARM'));
  cbetaR(1) = Intercept;

```

```

        else if (line = 'RetailBanking') then do;
            xbeta = cbetaR(1);
            do i=1 to dim(cxR);
                xbeta = xbeta + cxR(i) * cbetaR(i+1);
            end;
            numloss = rand('POISSON', exp(xbeta));
        end;
        output;
    end;
end;
run;

```

To use the replication identifier variable with PROC CCDM, you need to partition the input data table of counts. The PARTITION= data table option partitions the data table such that a group of observations that have the same value for the variables line and Repld are located on the same worker node.

The following DATA step loads the data set Work.LossCounts2 into a data table in your CAS session that is associated with the mylib CAS engine libref. The DATA step assumes that your CAS engine libref is named mylib, but you can substitute any appropriately defined CAS engine libref.

```

/* Load the data and partition by the specified variables. */
data mylib.lossCounts2(partition=(line repld));
    set lossCounts2;
run;

```

Output 7.2.3 shows some observations of the data table mylib.LossCounts2 for each business line. For the first replication (Repld=1) of the commercial banking line, only operating environments 3 and 4 incur loss events; the other environments incur no loss events. For the second replication (Repld=2), all operating environments incur at least one loss event. For the first replication (Repld=1) of the retail banking line, operating environments 2, 3, and 4 incur two, one, and three loss events, respectively.

Output 7.2.3 Snapshot of the External Counts Data with Replication Identifier

You can now use this simulated count data to estimate the distribution of the aggregate loss that is incurred in all four operating environments by submitting the following PROC CCDM step, in which you specify the replication identifier variable RepId in the ID= option of the EXTERNALCOUNTS statement:

```
/* Estimate the distribution of the aggregate loss for both
   lines of business by using the externally simulated counts
   for the multiple operating environments */
proc ccdm data=mylib.lossCounts2 seed=13579 print=all
    severityest=mylib.sevestEx2;
    by line;
    externalcounts count=numloss id=repid;
    severitymodel logn gamma;
run;
```

Within each BY group, for each value of the variable RepId, one point of the aggregate loss sample is simulated by using the process that is described in the section “[Simulation with External Counts](#)” on page 221.

The summary statistics and percentiles of the distribution of the aggregate loss, which is the aggregate of the losses across all four operating environments, are shown in [Output 7.2.4](#) for the commercial banking line. The “Input Data Summary” table indicates that the BY group contains 10,000 replications and that a total of 145,721 loss events are generated across all replications. The “Sample Percentiles” table indicates the median aggregate loss, as defined by the 50th percentile, and a worst-case loss, as defined by the 99.5th percentile, from the commercial banking line when you combine losses from all four operating environments.

Output 7.2.4 Aggregate Loss Summary for the Commercial Banking Line in Multiple Operating Environments

Example 7.3: Scenario Analysis with Rich Regression Effects and BY Groups

This example illustrates scenario analysis when frequency and severity models use regression models that contain classification and interaction effects. It also illustrates how you can analyze scenarios for multiple groups of observations in one PROC CCDM step without having to simulate counts externally.

The example in the section “[Scenario Analysis](#)” on page 183 encodes the discrete-valued, nominal (nonordinal) variables Gender, CarType, and Education as numerical variables that have an implied order. For example, a high school diploma is assigned a smaller number than an advanced degree. This method of forcing an order on otherwise nonordinal (categorical) variables is not natural and might lead to biased estimates. A more accurate approach is to treat such variables as classification variables that enter the statistical analysis or model not through their values but through their levels. For example, when you specify Education as a classification variable, the modeling process creates different parameters for the Education = ‘High School’ and Education = ‘Advanced Degree’ levels and estimates a regression coefficient for each. When you specify such variables in the CLASS statement of PROC CNTSELECT and PROC SEVSELECT, those procedures perform the appropriate levelization for you, which is the process of finding and transforming levels into regression parameters. For more information, see the description of the CLASS statement in Chapter 26, “[SEVSELECT Procedure](#).”

In addition to specifying nominal variables as classification (CLASS) variables, you can include interaction effects in severity and frequency models. For example, you might want to evaluate how the distribution of losses that are incurred by a policyholder who has a college degree and drives an SUV differs from that of a policyholder who has an advanced degree and drives a sedan. You can do this by including an interaction between CarType and Education in your severity model. Similarly, if you want to evaluate how the number of losses that a policyholder incurs per year varies by the number of annual miles for different types of cars, you can include an interaction between CarType and AnnualMiles in your frequency model. Analyzing such a rich set of regression effects can help you make more accurate predictions about the frequency and severity distributions of losses. PROC CCDM is designed to use such rich models to simulate a more accurate distribution of the aggregate loss.

To start the scenario analysis process, let the following programming statements simulate the frequency and severity events that are affected by the regression effects:

```
/* Define a macro to simulate regressor data */
%macro generateRegvars;
    age = MAX(int(rand('NORMAL', 35, 15)),16)/50;

    if (rand('UNIFORM') < 0.5) then do;
        genderNum = 1; * female;
        gender = 'F';
    end;
    else do;
        genderNum = 2; * male;
        gender = 'M';
    end;

    if (rand('UNIFORM') < 0.7) then do;
        carTypeNum = 1; * sedan;
        carType = 'Sedan';
    end;
    else do;
```

```

    carTypeNum = 2; * SUV;
    carType = 'SUV';
end;

educationLevel = rand('UNIFORM');
if (educationLevel < 0.5) then do;
    educationNum = 1; *high school graduate;
    education = 'High School';
end;
else if (educationLevel < 0.85) then do;
    educationNum = 2; *college graduate;
    education = 'College';
end;
else do;
    educationNum = 3; *advanced degree;
    education = 'Advanced Degree';
end;

annualmiles = MAX(1000, int(rand('NORMAL', 12000, 5000)))/5000;

carSafety = rand('UNIFORM'); /* scaled to be between 0 & 1 */

income = MAX(15000, int(rand('NORMAL', educationNum*30000, 50000)))/100000;
%mend;

/* Simulate loss severity data */
%let npolicy=1000;

data losses(keep=region policyholderId age gender carType

        lossAmount = exp(Mu) * rand('LOGNORMAL')**Sigma;
        output;
    end;
end;
else do;
    noloss = 1;
    lossAmount = .;
    output;
end;
end;
end;

run;

/* Load the loss severity data */
data mylib.losses;
    set losses;
run;

/* Simulate loss counts data */
proc sort data=losses out=lossesByPolicy;
    by region policyholderId;
run;

data losscounts(drop=policyholderId carSafety lossAmount noloss);
    set lossesByPolicy;

```

```

    by region policyholderId;
    retain numloss zeroloss 0;
    if (noloss eq 1) then
        zeroloss = zeroloss + 1;
    else
        numloss = numloss + 1;
    if (last.policyholderId) then do;
        output;
        numloss = 0;
    end;
run;

/* Load the loss counts data */
data mylib.losscounts;
    set losscounts;
run;

```

The following programming statements use the data tables that the preceding statements create to fit the severity and count models that contain a certain set of regression effects:

```

proc sevselect data=mylib.losses(where=(lossAmount ne .))
    covout outstore=mylib.sevstore print=all;
    by region;
    loss lossAmount;
    class carType gender education;
    scalemodel carType gender carSafety income education*carType
        income*gender carSafety*income;
    selection method=backward(select=sbc) details=summary;
    dist logn burr;
run;

proc cntselect data=mylib.losscounts store=mylib.cstore;
    by region;
    class gender carType education;
    model numloss = age income gender carType*annualmiles
        education / dist=poisson;
    zeromodel numloss ~ age income carType education;
    selection method=backward(select=sbc) details=summary;
run;

```

Note the following points about these statements:

- The data tables are organized in groups of observations that represent data from two regions, East and West. You can analyze both groups at the same time by specifying the BY statement with Region as the BY variable. The observations in the input data table do not need to be sorted by the BY variables.
- Both severity and count models use three CLASS variables. The severity model includes three interaction effects (Education*CarType, Income*Gender, and CarSafety*Income) and four main effects.
- The count model is a zero-inflated model, which is essentially a mixture of two models: a model to estimate the occurrence of zero loss events and a model to estimate nonzero counts. The model for zero counts, which is specified in the ZEROMODEL statement, is a regression model that has four main effects and uses the default logistic link function. The model for nonzero counts, which is specified in

the MODEL statement, is a Poisson model that has one interaction effect (CarType*AnnualMiles) and four main effects.

- Both the PROC SEVSELECT and PROC CNTSELECT steps use the SELECTION statement to perform automatic effect selection. In particular, they use the backward selection method to choose a subset of regression effects that maximize the Schwarz Bayesian information criterion (SBC). PROC SEVSELECT conducts the effect selection process independently for each distribution.
- The PROC SEVSELECT step uses the OUTSTORE= option to store the parameter estimates in an item store. When your scale regression model contains classification or interaction effects, you must store the parameter estimates in an item store instead of storing them in an OUTEST= data table because PROC CCDDM cannot obtain the necessary information about classification or interaction effects from an OUTEST= data table.

For severity models, you can inspect the “All Fit Statistics” table for each BY group to decide which severity distribution has the best fit for the data in that BY group. When you specify the SELECTION statement, each row in this table shows the fit statistics of the scale regression model that contains only the final selected set of regression effects for the candidate distribution of that row. The tables in [Output 7.3.1](#) indicate that the model that uses the lognormal distribution is the best according to the majority of fit statistics for both regions, so you can just specify the LOGN distribution in the SEVERITYMODEL statement of the subsequent PROC CCDDM step. In cases where different distributions are deemed best for different BY groups, you have two alternatives. The first alternative is to run one PROC CCDDM step with the SEVERITYMODEL statement that specifies the best distributions from all BY groups and to later process the results of only the best severity distribution in each BY group. The second alternative is to run separate PROC CCDDM steps for each BY group by specifying the best severity distribution for that BY group in the SEVERITYMODEL statement. The latter alternative requires more coding effort but it is more efficient than the first alternative, which runs the analysis for all best severity distributions for all BY groups.

Also note that in some cases, you might see that the likelihood-based fit statistics (–2 log likelihood, AIC, AICC, and BIC) mark one distribution as the best distribution and the EDF-based statistics (KS, AD, and CvM) mark another distribution as the best distribution. In such cases, it is recommended that you conduct aggregate loss simulation by using both severity distributions and compare the summary statistics and percentiles of resulting aggregate loss distributions.

If you want to examine the summary of the effect selection process and the final selected set of regression effects for a severity distribution, you can examine the “Selection Summary” and “Selected Effects” tables as shown in [Output 7.3.2](#). These tables indicate that the best scale regression model for the lognormal distribution in the region=East group is obtained after removing the carSafety*income and income*gender effects.

Output 7.3.2 Summary of the Effect Selection Process for LOGN Severity Model for Region=East**The SEVSELECT Procedure****Logn Distribution

region=East			
Selected Effects: Intercept carType gender carSafety income carType*education			

You can examine a similar summary of the selection process that the CNTSELECT procedure follows to select the best effect subset for the count distribution, as shown in [Output 7.3.3](#). The best model for the zero-inflated Poisson (ZIP) distribution in the region=East group is obtained after removing the education, age, and income effects from the model for the zero counts and removing the income effect from the model for nonzero counts. So the final model contains only the carType effect in the zero-model and age, income, gender, carType*annualmiles, and education effects in the nonzero-model.

* Optimal Value Of Criterion			

PROC SEVSELECT conducts a separate effect selection analysis for each severity distribution within each BY group, so scale regression models for different severity distributions in the same BY group can contain different final sets of selected effects. Similarly, scale regression models for the same severity distribution in different BY groups can contain different final sets of selected effects. PROC CNTSELECT also conducts a separate effect selection analysis for each BY group, so the final sets of selected effects in the count regression model can be different for different BY groups.

After the CNTSELECT and SEVSELECT procedures have selected the best frequency and severity models, it is time to estimate the distribution of the aggregate loss by using the CCDM procedure. Given that the models depend on regressors, first you need to create the scenario data table, which must contain the final set of regressors that are used in both the severity model and the frequency model. Even if your models contain classification or interaction effects, your scenario data table needs to contain only the columns for individual variables of the effects. PROC CCDM internally performs *levelization* of each observation, which is the process of expanding the variable values to match them with the parameters of each effect. For example, you do not need to create multiple columns for the parameters of the carType*education effect. You just need to create two columns for carType and education. PROC CCDM internally creates the six columns that correspond to the six parameters that are associated with the carType*education effect. However, you must make sure that the values of each classification variable, such as carType, in the scenario data table belong to the same set of values that appear in the input data tables of PROC SEVSELECT and PROC CNTSELECT.

A typical scenario for an insurance application usually consists of a large number of policyholders. However, for illustration purposes, this example uses a small scenario of only a few policyholders per region that is generated by the following DATA step and shown in [Output 7.3.4](#):

```
/* Create scenario for internal count simulation */
data scenario(keep=region policyholderId age gender
               carType annualmiles education carSafety income);
  call streaminit(456);

  length region $4 gender $1 carType $8 education $16;

  do iregion=1 to 2;
    if (iregion = 1) then do;
```

```

        region = 'East';
        npolicy = 3;
    end;
    else do;
        region = 'West';
        npolicy = 5;
    end;
    do policyholderId = 1 to npolicy;
        %generateRegvars;
        output;
    end;
end;
run;

/* Load the scenario data */
data mylib.scenario;
    set scenario;
run;

```

Output 7.3.4 Data Table mylib.Scenario for BY-Group Processing

Obs	region	gender	carType	education	age	annualmiles	carSafety	income
1	East	F	SUV	High School	1.16	2.1540	0.29288	0.26090

The following PROC CCDM step simulates the aggregate losses for the scenario in the data table mylib.Scenario by each region:

```

proc ccdm data=mylib.scenario nreplicates=10000 seed=123 print=all
    severitystore=mylib.sevstore countstore=mylib.cstore
    nperturb=30;
    by region;
    severitymodel logn;
    outsum out=mylib.agglossStats mean stddev skewness kurtosis
    pctlpts=(90 97.5 99.5);
run;

```

The BY statement must contain the same set of variables and in the same order as the variables in the BY statements that you specify in PROC SEVSELECT and PROC CNTSELECT. The **SEVERITYSTORE=** and **COUNTSTORE=** options specify the item stores that contain the effect information and parameter estimates of the severity and count models, respectively, for both BY groups. The count item store that PROC CNTSELECT creates always contains the covariance estimates of the count model parameters, and the COVOUT option in the PROC SEVSELECT step ensures that the severity item store includes the covariance estimates. Availability of these covariance estimates makes the perturbation analysis that the NPERTURB= option requests more accurate.

One of the main points that this example illustrates is that irrespective of the complexity of the regression effects in your frequency or severity models, you do not have to do any extra work to convey the effect information to PROC CCDDM, except to specify the item stores. The frequency and severity item stores contain all the necessary information that PROC CCDDM needs for computing the values of the regressor-dependent parameters of the underlying frequency and severity distributions before making random draws from those distributions. When you use the BY and SELECTION statements in PROC CNTSELECT and PROC SEVSELECT, the respective item stores contain the information about the final selected regression effects for each distribution in each BY group. PROC CCDDM uses this information to process only the regression parameters that correspond to the selected regression effects for each distribution in each BY group.

Output 7.3.5 and Output 7.3.6 show the summary of the perturbation analysis for the two regions.

Output 7.3.5 Aggregate Loss Simulation Results for Region=East

Example 7.4: Illustrating Pure Premium and Custom Simulation Modes

The CCDM procedure supports simulation modes other than the default collective risk simulation mode. This example illustrates how you can use those modes to simulate samples for different types of aggregate losses. Suppose you are an actuary at an insurance company and you want to estimate the distribution of the pure premium for the claims that you expect to be filed by the policyholders in a particular time period. The pure premium method of estimating claims cost is useful for certain types of peril. Assume that you have estimated a simple severity distribution model for the average severity of each claim by submitting the following statements, where the data table mylib.ClaimSev contains a simulation of historic average severity data:

```
/* Simulate average severity data and load them */
data claimsev(keep=averagesev);
  call streaminit(789);
  label averagesev='Average severity per claim';
  do n = 1 to 10000;
    averagesev = rand('Weibull', 3, 500);
    output;
  end;
run;
data mylib.claimsev;
  set claimsev;
run;

/* Fit severity models and write estimates to an item store */
proc sevselect data=mylib.claimsev crit=sbc covout outstore=mylib.sevstore;
  loss averagesev;
  dist gamma igauss logn weibull;
run;
```

Output 7.4.1 Comparison of Severity Distributions for Average Severity**The SEVSELECT Procedure**

Model Selection			
Distribution	Converged	SBC	Selected
Gamma	Yes	130839	No
Igauss	Yes	132718	No
Logn	Yes	132081	No
Weibull	Yes	130163	Yes

The “Model Selection” table in [Output 7.4.1](#) shows that the Weibull distribution is the best-fitting distribution for the average severity. Next, assume that you have used a time-series analysis method to create a model for average number of claims that you expect to process in a particular time period. Let the average frequency follow a normal distribution $\mathcal{N}(5000, 100)$, which implies that the point forecast of the average frequency for the time period of interest is 5,000 with an associated standard error of 100. To analyze the distribution of the pure premium, which is the product of average severity and average frequency, you can use the `SIMULATIONMODE=PUREPREMIUM` option in PROC CCDM as shown in the following statements:

```
proc ccdm severitystore=mylib.sevstore simulationmode=purepremium
    seed=135 nreplicates=500000 print=all plots=density;
    severitymodel weibull;
    countmodel normal(5000, 100);
run;
```

The COUNTMODEL statement specifies the distribution of the average frequency. The SEVERITYMODEL statement requests that only the Weibull distribution be read from the SEVERITYSTORE= item store. The PRINT=ALL option displays the quantitative summary of the pure premium distribution, which is shown in the “Sample Summary Statistics” and “Sample Percentiles” tables in [Output 7.4.2](#). The PLOTS= option creates a plot of the nonparametric estimate of the probability density function (PDF) of the pure premium distribution, which is shown in [Output 7.4.3](#).

Output 7.4.2 Summary Statistics and Percentiles of the Pure Premium Distribution**The CCDM Procedure**

Severity Model: Weibull
Count Model: Normal(5000,100)

Sample Summary Statistics			
Mean	2225717.6	Median	2204042.8
Standard Deviation	817761.9	Interquartile Range	1143309.1

Kurtosis	-0.26164	Sample Size	500000

Output 7.4.2 *continued*

Sample Percentiles	
Percentile	Value
1	527953.7
5	915327.3
25	1638602.1
50	2204042.8
75	2781911.1
95	3613171.7
99	4180009.8
99.5	4381630.4
Percentile Method = 5	

Output 7.4.3 Nonparametric PDF Plot of the Pure Premium Distribution

Now consider a situation where the average frequency is defined as the average number of claims *per policy* and you have estimated a separate distribution model for the number of policies, denoted by n_{Policy} , that you expect to be in force for the particular time period. If you want to estimate a distribution of the total

expected loss across all policies according to the pure premium method, then you need to multiply the pure premium by an estimate of `nPolicy`. Because `nPolicy` is stochastic, the simulation process needs to make a random draw from its distribution. Assuming that the average number of claims per policy follows a standard negative binomial distribution with parameters $p = 0.75$ and $n = 5$ and that `nPolicy` follows a lognormal distribution with parameters $\mu = 10$ and $\sigma = 0.35$, the following PROC CCDM step simulates a sample of the total expected loss, `tLoss`, across all policies:

```
proc ccdm severitystore=mylib.sevstore simulationmode=purepremium
    seed=135 nreplicates=500000 print=all adjustedseverity=tloss;
    severitymodel weibull;
    countmodel negbin(0.75, 5);
    simulatedsymbol npolicy ~ lognormal(10,0.35);
    tloss = _sev_ * npolicy;
run;
```

The COUNTMODEL statement specifies that the frequency follows the Negbin(0.75, 5) distribution. The SIMULATEDSYMBOL statement specifies the stochastic variable `nPolicy`. The severity adjustment program contains just one statement in this example, and it computes `tLoss` by multiplying the average severity value in the `_SEV_` placeholder symbol by the simulated value of `nPolicy`. PROC CCDM supplies the simulated values of both the `_SEV_` and `nPolicy` symbols to your adjustment program. In the pure premium simulation mode, for each replication, PROC CCDM multiplies the `tLoss` value that your adjustment program returns by the frequency value that it draws from the Negbin(0.75, 5) distribution to compute the final value of `tLoss` for that replication. The distribution of `tLoss` is summarized in the tables shown in [Output 7.4.4](#).

Output 7.4.4 Summary Statistics and Percentiles of the Total Loss Distribution

The CCDM Procedure

Severity Model: Weibull
Count Model: NegativeBinomial(0.75,5)

Summary Statistics for tloss			
Mean	17380429	Median	12051182
Standard Deviation	19869773	Interquartile Range	21118588
Variance	3.948079E14	Minimum	0
Skewness	2.42533	Maximum	422595056
Kurtosis	10.71788	Sample Size	500000

Percentiles for tloss	
Percentile	Value
1	0
5	0
25	3132245.7
50	12051182
75	24250834
95	55453569
99	91066951
99.5	108199963
Percentile Method = 5	

If you want to further account for the loss adjustment expenses (LAE) in your simulations and if you have

estimated that the average LAE per policy follows a normal distribution $\mathcal{N}(100, 10)$, then the total loss and expense, denoted by `tLossExp`, is computed as `tLossExp = ((severity/claim) * (claims/policy) + LAE)*nPolicy`. Because this does not fit the standard pure premium formula, you need to use the custom simulation mode by specifying the `SIMULATIONMODE=CUSTOM` option in the `PROC CCDM` statement as illustrated by the following statements:

```
proc ccdm severitystore=mylib.sevstore simulationmode=custom nperturb=50
    seed=135 nreplicates=500000 print=all adjustedseverity=(tloss tlossexp)
    plot(nadjsev=2)=(conditionaldensity(leftq=0.2 rightq=0.9));
    severitymodel weibull;
    countmodel negbin(0.75(se=0.05), 5(se=0.5));
    simulatedsymbol npolicy ~ lognormal(10,0.35) lae ~ normal(100,10);
    tloss = _sev_ * _freq_ * npolicy;
    tlossexp = (_sev_ * _freq_ + lae) * npolicy;
run;
```

The `SIMULATEDSYMBOL` statement now contains the specification for the stochastic variable LAE. For the custom simulation mode, `PROC CCDM` analyzes only the symbols that you specify in the `ADJUSTED-SEVERITY=` option; unlike collective risk or pure premium simulation modes, it does not create a sample for the unadjusted aggregate loss. However, you can compute the pure premium loss in the custom mode yourself as illustrated by the programming statement that computes `tLoss` in the preceding `PROC CCDM` step.

For each replication, `PROC CCDM` draws one random value each from the probability distributions of severity, frequency, LAE, and `nPolicy`, and it supplies those values to your severity adjustment program in appropriate symbols (the `_FREQ_` and `_SEV_` symbols contain frequency and severity values, respectively). The values of `tLoss` and `tLossExp` symbols that your severity adjustment program returns are added to the `tLoss` and `tLossExp` samples, respectively. The summary of the `tLossExp` sample thus generated is shown in [Output 7.4.5](#). As expected, the mean, median, and percentile estimates of total loss and expenses are higher than the corresponding estimates for the total loss distribution in [Output 7.4.4](#). The conditional PDF plot in [Output 7.4.6](#) shows the nonparametric estimate of the density function in different ranges of values of `tLossExp`. The left-tail plot indicates that there are at least 20% zero-valued observations in the sample of `tLossExp`, which implies that many policies do not result in a loss event. The right-tail plot starts at the 90th percentile and the density is nonzero for large losses, which implies that the distribution of `tLossExp` has a heavy tail.

Output 7.4.5 Summary Statistics and Percentiles of the Total Loss and Expenses Distribution

The CCDM Procedure

Severity Model: Weibull
Count Model: NegativeBinomial(0.75,5)

Output 7.4.6 Nonparametric Density Estimate of the Total Loss and Expenses Distribution

The NPERTURB= option in the preceding PROC CCDM step requests perturbation analysis, which requires

the variability estimates of distribution parameters. For the severity distribution, PROC CCDM reads the variability estimates from the SEVERITYSTORE= item store. For the externally estimated count distribution, you need to specify the standard errors of its parameters by using the SE= option after each parameter value in the COUNTMODEL statement, as shown in the preceding PROC CCDM step. For each perturbed sample, PROC CCDM uses perturbed values of the severity and frequency distribution parameters, but it does not perturb the parameters of the simulated symbols. The perturbation summary for the total loss and expense distribution is shown in [Output 7.4.7](#).

Output 7.4.7 Perturbation Analysis of the Total Loss and Expenses Distribution

Overview: CCOPULA Procedure

A multivariate distribution for a random vector contains a description of both the marginal distributions and their dependence structure. A copula approach to formulating a multivariate distribution provides a way to isolate the description of the dependence structure from the marginal distributions. A copula is a function that combines marginal distributions of variables into a specific multivariate distribution. All of the one-dimensional marginals in the multivariate distribution are the cumulative distribution functions of the factors. Copulas help perform large-scale multivariate simulation from separate models, each of which can be fitted using different, even nonnormal, distributional specifications.

The CCOPULA procedure enables you to fit multivariate distributions or copulas from a specified sample data table. You can do the following:

- estimate the parameters for a specified copula type
- simulate a given copula

PROC CCOPULA Features

The CCOPULA procedure enables you to simulate or fit (or both) a specified copula, and it supports the following types of copulas:

- normal copula
- t copula
- Clayton copula
- Gumbel copula
- Frank copula

PROC CCOPULA Compared with Other SAS Procedures

The CCOPULA procedure provides copula simulation and model fitting functionality comparable to that of the HPCOPULA and COPULA procedures in SAS/ETS software.

PROC CCOPULA Compared with the HPCOPULA Procedure

The functionality of the CCOPULA procedure closely resembles that of the HPCOPULA procedure, which is a high-performance procedure. The CCOPULA procedure is the next generation of the HPCOPULA procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads on multiple machines.

The CCOPULA procedure provides all the functionality of the HPCOPULA procedure.

PROC CCOPULA Compared with the COPULA Procedure

The CCOPULA procedure is specifically designed to operate on SAS Viya and performs computations in multiple threads on multiple machines. By contrast, the COPULA procedure runs only in a single thread on a single machine.

This release of the CCOPULA procedure contains some, but not all, of the functionality present in the COPULA procedure. The COPULA procedure provides the following feature, which is not present in the CCOPULA procedure:

- hierarchical Archimedean copulas

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section [“Introduction to Shared Concepts”](#) on page 54 in Chapter 4, [“Shared Concepts.”](#)

Getting Started: CCOPULA Procedure

The following example illustrates the use of PROC CCOPULA. The data are daily returns on several major stocks. The main purpose of this example is to estimate the joint distribution of stock returns and then use this distribution to simulate a new sample of specified size.

Figure 8.1 shows the first 10 observations of the daily stock return data set.

Figure 8.1 First 10 Observations of Daily Returns

Obs	date	ret_msft	ret_ko	ret_ibm	ret_duk	ret_bp

The following statements fit a normal copula to the returns data (by using the FIT statement) and create a new SAS item store that contains parameter estimates of the model along with a complete description of the model (including variable names, copula type, and so on). The VAR statement specifies the list of variables, which in this case are the daily returns of stocks from five large companies.

```
/* Copula estimation */
proc ccopula data = mylib.returns;
  var ret_ibm ret_msft ret_bp ret_ko ret_duk;
  fit normal / store=mylib.estimates_norm;
run;
```

The first table in Figure 8.2 shows some general information about the copula fitting procedure: the number of observations, the name of the input data table, the type of model, and the correlations matrix.

Figure 8.2 Copula Estimation: Fit Summary and Correlations Matrices

The CCOPULA Procedure

Then, in the following statements, the `SIMULATE` statement specifies a copula named `COP`, and the `RESTORE=` option specifies that the item store `Estimates_Norm` be used as the source for the variable names, copula type, and parameters. The `NDRAWS=500` option in the `SIMULATE` statement generates 500 observations from the normal copula. The `OUTUNIFORM=` option specifies the name of the data table to contain the simulated sample with uniform marginal distributions. Note that this syntax does not require the `DATA=` option and that neither the `VAR` statement nor the `DEFINE` statement is needed.

```
/* Ccopula simulation of uniforms */
proc ccopula;
    simulate cop / restore=mylib.estimates_norm
                ndraws      = 500
                seed        = 1234
                outuniform  = mylib.simulated_uniforms;
run;
```

The simulated data are contained in the new data table, `mylib.Simulated_Uniforms`.

The preceding sequence of `PROC CCOPULA` usage—first fit, then simulate using estimated parameters—is a legitimate sequence but has a limitation in that the second `PROC CCOPULA` call does not generate the sample according to the empirical distribution of the raw data. It generates only marginally uniform series.

In the following statements, the `FIT` statement fits a t copula to the returns data and at the same time simulates the sample according to empirical marginal distributions. Because there is no `VAR` or `DEFINE` statement, `PROC CCOPULA` assumes that you want to initialize the simulation by using the information stored in an item store. Because the `RESTORE=` option is not used in the `SIMULATE` statement, `PROC CCOPULA` uses the item store that is created when the `FIT` statement is executed.

```

/* Ccopula estimation and simulation */
proc ccopula data = mylib.returns;
  var ret_ibm ret_msft ret_bp ret_ko ret_duk;
  fit T / store=mylib.estimated_t;
  simulate / ndraws = 1000
            seed    = 1234
            outuniform = mylib.simuni;
run;

```

The output of the statements is similar in structure to the output displayed in Figure 8.2, with the addition of parameter estimates and inference statistics that are specific to the copula model as shown in Figure 8.3. For a t copula, the degrees of freedom are displayed (as in Figure 8.3); for Archimedean copulas, the parameter “theta” is displayed; and for a normal copula, this table is not printed.

Figure 8.3 Copula Estimation: Specific Parameter Estimates

The CCOPULA Procedure

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
DF	3.659299	0.320474	11.42	<.0001

The simulated data are contained in the new data table, mylib.Simuni.

Syntax: CCOPULA Procedure

The following statements are available in the CCOPULA procedure:

```

PROC CCOPULA options ;
  BY variables ;
  DEFINE name copula-type <(parameter-value-options ...) > ;
  DISPLAY <table-list> </ options > ;
  DISPLAYOUT table-spec-list </ options > ;
  FIT type <NAME=name > <INIT=(parameter-value-options) > / options ;
  SIMULATE < copula-name-list > / options ;
  VAR variables ;
  VIEWSTORE / options ;

```

Functional Summary

Table 8.1 summarizes the statements and options that the CCOPULA procedure uses.

Table 8.1 Functional Summary

Description	Statement	Option
Data Table Options		
Specifies the input data table	PROC CCOPULA	DATA=
Specifies the input data table that contains the correlations matrix for elliptical copulas	DEFINE	CORR=
Specifies the input data table that contains the correlations matrix defined in Kendall's tau for elliptical copulas	DEFINE	KENDALL=
Specifies the input data table that contains the correlations matrix defined in Spearman's rho for elliptical copulas	DEFINE	SPEARMAN=
Copula Fitting Options		
Specifies the method to use	FIT	METHOD=
Specifies the input data table that contains the correlations matrix for elliptical copulas	FIT	CORR=
Specifies the parameter value for Archimedean copulas	FIT	THETA=
Specifies the degrees of freedom for t copulas	FIT	DF=
Declaring the Role of Variables		
Specifies the names of the variables to use in copula fitting or in simulation	VAR	
Specifies BY-group processing	BY	
Options to Control the Optimization Process		
Selects the iterative minimization method to use	FIT	OPTMETHOD=
Specifies the maximum number of iterations for the optimization when you are fitting a t or Archimedean copula and METHOD=MLE	FIT	MAXITER=
Sets initial values for parameters	FIT	INIT=
Copula Estimation Options		
Specifies the marginal distribution of the individual variables	FIT	MARGINALS=
Copula Simulation Options		
Specifies the random sample size	SIMULATE	NDRAWS=
Specifies the random number generator seed	SIMULATE	SEED=

Description	Statement	Option
Output Control Options		
Specifies the output data table to contain the normalized pseudo-data used for model fitting	FIT	OUTPSEUDO=
Specifies the output item store to preserve the properties of the copula that is fit and the results of fitting the copula	FIT	STORE=
Specifies the output data table to contain the random samples from the simulation with uniform marginal distribution	SIMULATE	OUTUNIFORM=
Prints timing information	PROC CCOPULA	PRINTTIMING
Specifies the ODS tables to display	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	

PROC CCOPULA Statement

PROC CCOPULA <options> ;

The following *options* can be used in the PROC CCOPULA statement.

Input Data Table Options

DATA=*libref.data-table*

names the input data table for PROC CCOPULA to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 287.

data-table specifies the name of the input data table.

When the procedure is used for simulation only, the input data table is not required in order to run the procedure. However, when you specify the OUTEMPIRICAL= option in the SIMULATE statement, or the DATATYPE=ORIGINAL plotting option in the SIMULATE statement, the input data table determines the marginal distributions for the output variables.

Printing Options

PRINTTIMING

prints a timing report.

BY Statement

BY *variables* ;

The BY statement specifies groups in which separate copula fitting analyses or simulations are performed. When you use the BY statement with the FIT statement, the *variables* must be present in the input data table and are excluded from the model fitting. You must also provide a VAR statement. The BY statement can also be used when simulating a copula. When you use the BY statement with the SIMULATE statement, you must specify an item store in the RESTORE= option. The item store must contain model fitting results for the same BY groups that are defined by the *variables* in your BY statement.

DEFINE Statement

DEFINE *name copula-type* <(parameter-value-options ...) > ;

The DEFINE statement specifies the relevant information about the copula that is used for the simulation. You can specify the following arguments:

name specifies the name of the copula definition. You can use this *name* later in the SIMULATE statement.

copula-type specifies the type of copula. You must specify one of the following copula types, which are described in the section “[Details: CCOPULA Procedure](#)” on page 304:

NORMAL	fits the normal copula.
T	fits the <i>t</i> copula.
CLAYTON	fits the Clayton copula.
FRANK	fits the Frank copula.
GUMBEL	fits the Gumbel copula.

parameter-value-options

specify the input parameters that are used to simulate the specified copula. These options must be appropriate for the type of copula specified. You can specify the following *parameter-value-options*:

CORR=*libref.SAS-data-table*

specifies the data table that contains the correlations matrix to use for elliptical copulas. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 287. All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. You can use this option for normal and *t* copulas.

DF=value

specifies the degrees of freedom. You can use this option for t copulas.

KENDALL=libref.SAS-data-table

specifies the data table that contains the correlations matrix defined in Kendall's tau. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the **DATA=** option and the section “Using CAS Sessions and CAS Engine Librefs” on page 287.

All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. The order of the rows must be such that row n contains the correlations between the n th variable in the VAR statement and the other variables. You can use this option for normal and t copulas.

SPEARMAN=libref.SAS-data-table

specifies the data table that contains the correlations matrix defined in Spearman's rho. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the **DATA=** option and the section “Using CAS Sessions and CAS Engine Librefs” on page 287.

All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. The order of the rows must be such that row n contains the correlations between the n th variable in the VAR statement and the other variables. You can use this option for normal copulas.

THETA=value

specifies the parameter value for the Archimedean copulas.

The DEFINE statement is used with the SIMULATE statement and the FIT statement.

DISPLAY Statement

DISPLAY < table-list > < / options > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[ODS Table Names](#)” on page 321. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

<i>key=value</i>	specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name.
<i>key</i>	specifies <i>key</i> as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 321. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

FIT Statement

FIT *type* <**NAME**=*name*><**INIT**=(*parameter-value-options*)> / *options* ;

The FIT statement estimates the parameters for a specified copula type.

You must specify a *type*:

type

specifies the type of the copula to be estimated, which is one of the following:

CLAYTON	fits the Clayton copula.
FRANK	fits the Frank copula.
GUMBEL	fits the Gumbel copula.
NORMAL	fits the normal copula.
T	fits the <i>t</i> copula.

You can also specify the following options:

INIT=(*parameter-value-options*)

provides the initial values for the numerical optimization.

[*parameter-value-options*]

specify the input parameters that are used to initialize the specified copula. These options must be appropriate for the type of copula that you specify. You can specify the following options:

CORR=*libref.SAS-data-table*

specifies the data table that contains the correlations matrix to use for elliptical copulas. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 287.

All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. The order of the rows must be such that row *n* contains the correlations between the *n*th variable in the VAR statement and the other variables. You can use this option for *t* copulas.

DF=*value*

specifies the degrees of freedom. You can use this option for t copulas.

KENDALL=*libref.SAS-data-table*

specifies the data table that contains the correlations matrix defined in Kendall's tau. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 287.

All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. The order of the rows must be such that row n contains the correlations between the n th variable in the VAR statement and the other variables. You can use this option for t copulas.

SPEARMAN=*libref.SAS-data-table*

specifies the data table that contains the correlations matrix defined in Spearman's rho. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 287.

All columns of the matrix must be numeric. The order of the column names in the matrix must match their order in the VAR statement. The order of the rows must be such that row n contains the correlations between the n th variable in the VAR statement and the other variables. You can use this option for t copulas.

THETA=*value*

specifies the parameter value for Archimedean copulas.

For Archimedean copulas, the default initial values of the parameter are computed using the calibration method. The default initial value of the degrees-of-freedom parameter in the t copula is set to 2.0. The following statement shows an initialization for Student's t copula, where the Kendall's tau correlations matrix is stored in the mylib.corrmat data table and the DF is set to 2.5:

```
fit t init=(df=2.5 kendall=mylib.corrmat);
```

NAME=*name*

specifies an identifier for the fit.

You can specify the following *options* after a slash (/):

MARGINALS=EMPIRICAL<(*approx-options*)> | **UNIFORM**

specifies the marginal distribution of the individual variables. You can specify the following values:

EMPIRICAL<(*approx-options*)> uses an approximation of the marginal empirical cumulative distribution function (CDF) to transform the data and uses the transformed data to fit the copula. You can specify the following *approx-options*:

ALG=BIN | SORT

specifies the algorithm to use during the approximation of the marginal distribution. You can specify the following values:

BIN	uses bins to approximate the marginal distributions.
SORT	stores and sorts each variable's observations in the input data table.

By default, ALG=BIN.

INTERP=LINEAR | SPLINE | STEP

specifies how to interpolate values within intervals in the distributions' approximations. You can specify the following values:

LINEAR	specifies that values within an interval be linearly interpolated between the endpoints.
SPLINE	specifies that values within an interval be interpolated using a cubic spline function that is constrained to be monotonically increasing.
STEP	specifies that values within an interval take the value of the left endpoint.

By default, INTERP=LINEAR.

MAXITERS=*integer*

specifies the maximum number of iterations to perform when you are generating the distribution approximation function. By default, MAXITERS=10. For more information, see the section "[Adaptive Approximation of Marginal Distributions](#)" on page 307.

REFINERES=*integer*

specifies the maximum number of intervals to add to the distribution function during each iteration of the empirical approximation. By default, REFINERES=1000.

UNIFORM uses the input data without transformation to fit the copula.

METHOD=MLE | CAL

specifies the method to use to estimate parameters. You can specify the following values:

CAL	specifies the calibration method that uses the correlations matrix (only Kendall's tau is implemented in this procedure).
MLE	specifies canonical maximum likelihood estimation (CMLE) or maximum likelihood estimation (MLE).

For the t copula, if METHOD=CAL, then the correlations matrix is estimated using the calibration method with Kendall's tau and the degrees of freedom are estimated by the MLE. For the normal copula, only METHOD=MLE is supported and METHOD=CAL is ignored. By default for all copula types, METHOD=MLE.

OUTPSEUDO=libref.data-table

specifies the output data table for saving the pseudo-samples with uniform marginal distributions. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 287.

The pseudo-samples are obtained by transforming the individual variables of the original data by using the empirical CDFs. The data table is not created if you omit this option.

PLOTS<(global-plot-options) > <=(specific-plot-options)>

controls the plots of the input data table that are produced by the CCOPULA procedure. By default, PROC CCOPULA produces a scatter plot matrix for variables (that is, it displays a symmetric matrix plot that contains the variables specified in the VAR statement).

You can specify the following *global-plot-options*:

KENDALL

creates Kendall plots. These plots compare observed quantiles of pairs of variables to quantiles of independent variables. If you specify this option together with the UNPACK option, PROC CCOPULA displays a Kendall plot of each applicable pair of distinct variables that you specify in the VAR statement. If you specify this option without the UNPACK option, PROC CCOPULA displays a scatter plot matrix; the lower triangular section of the matrix shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, and the upper triangular section of the matrix shows Kendall plots of corresponding pairs of variables.

NSAMPLES=*n*

specifies the number points to plot when you create Kendall plots. For each pair of variables, *n* samples are randomly selected from the DATA= data table. The same samples are plotted for all the Kendall plots. By default, NSAMPLES=1000.

NVAR=ALL | *n*

specifies the maximum number of variables that you specify in the VAR statement to display in the matrix plot. NVAR=ALL uses all variables that you specify in the VAR statement. By default, NVAR=5.

RESOLUTION=*n*

specifies the number of bins to use for the X and Y axes when you create plots. By default, RESOLUTION=50.

SCATTER

creates a scatter plot matrix of variables that you specify in the VAR statement. The maximum number of variables that you can display in the scatter plot matrix is 10.

TAIL | CHI

creates tail dependence plots (chi plots). If you specify this option together with the UNPACK option, PROC CCOPULA displays a chi plot of each applicable pair of distinct variables that you specify in the VAR statement. If you specify this option without the UNPACK option, PROC CCOPULA displays a scatter plot matrix; the lower triangular section of the matrix shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, and the upper triangular section of the matrix shows chi plots of corresponding pairs of variables.

UNPACK | UNPACKPANEL

creates scatter plots of pairs of variables. If you specify this option, PROC CCOPULA displays a scatter plot of each applicable pair of distinct variables that you specify in the VAR statement.

You can also specify the following *specific-plot-options*:

DATATYPE=ORIGINAL | UNIFORM | BOTH

specifies the data type to be plotted. DATATYPE=ORIGINAL presents the data in their original marginal distribution. DATATYPE=UNIFORM shows the transformed data with a uniform marginal distribution. DATATYPE=BOTH plots both the original and uniform data types. When MARGINALS=UNIFORM, the transformation is omitted and the DATATYPE= option is ignored.

NONE

suppresses all plots.

STORE=SAS-item-store

specifies the item store that preserves the properties of the model and the fit results.

Printing Options

ITPRINT

prints a summary iteration listing.

NOCORR

suppresses the correlations matrix.

NOPRINT

suppresses all output.

PRINTALL

prints all output. This is the default.

SIMULATE Statement

SIMULATE < *copula-name-list* > / *options* ;

The SIMULATE statement simulates data from a specified copula model. The copula name specification is the name of a defined copula as specified by *name* in the DEFINE statement. You can specify the following *options*:

EMPAPPROX< (*approx-options*) >

uses an approximation of the inverse marginal empirical cumulative distribution function to transform the data when you specify the OUTEMPIRICAL= output option. You can specify the following *approx-options*:

ALG=BIN | SORT

specifies the algorithm to use during the approximation of the marginal distribution. You can specify the following values:

BIN	uses bins to approximate the marginal distributions.
SORT	stores and sorts each variable's observations in the input data table.

By default, ALG=BIN.

INTERP=LINEAR | SPLINE

specifies how to interpolate values within intervals in the distributions' approximations. You can specify the following values:

LINEAR	specifies that values within an interval be linearly interpolated between the endpoints.
SPLINE	specifies that values within an interval be interpolated using a cubic spline function that is constrained to be monotonically increasing.

By default, INTERP=LINEAR.

MAXITERS=*integer*

specifies the maximum number of iterations to perform when you are generating the distribution approximation function. By default, MAXITERS=10. For more information, see the section [“Adaptive Approximation of Marginal Distributions”](#) on page 307.

REFINERES=*integer*

specifies the maximum number of intervals to add to the distribution function during each iteration of the empirical approximation. By default, REFINERES=1000.

NDRAWS=*integer*

specifies the number of draws to generate for this simulation. By default, NDRAWS=100.

OUTEMPIRICAL=*libref.data-table*

specifies the output data table to contain the result of the simulation that uses empirical margins. The distribution that is used to transform each variable's uniformly simulated value to its empirical value is specified by the corresponding variable in the DATA= input data table in the PROC CCOPULA statement. The data are not created if you omit this option. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section [“Using CAS Sessions and CAS Engine Librefs”](#) on page 287.

OUTUNIFORM=*libref.data-table*

specifies the output data table to contain the result of the simulation in uniform margins. The data are not created if you do not specify this option. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the [DATA=](#) option and the section [“Using CAS Sessions and CAS Engine Librefs”](#) on page 287.

PLOTS<(global-plot-options)> <= (specific-plot-options)>

controls the plots of simulated data that are produced by the CCOPULA procedure. By default, PROC CCOPULA produces a scatter plot matrix of variables (that is, it displays a symmetric matrix plot that contains the variables specified in the VAR statement).

You can specify the following *global-plot-options*:

KENDALL

creates Kendall plots. These plots compare observed quantiles of pairs of variables to quantiles of independent variables. If you specify this option together with the UNPACK option, PROC CCOPULA displays a Kendall plot of each applicable pair of distinct variables that you specify in the VAR statement. If you specify this option without the UNPACK option, PROC CCOPULA displays a scatter plot matrix; the lower triangular section of the matrix shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, and the upper triangular section of the matrix shows Kendall plots of corresponding pairs of variables.

NSAMPLES=*n*

specifies the number points to plot when you create Kendall plots. For each pair of variables, *n* samples are randomly selected from the OUTUNIFORM= data table. The same samples are plotted for all the Kendall plots. By default, NSAMPLES=1000.

NVAR=ALL | *n*

specifies the maximum number of variables that you specify in the VAR statement to display in the matrix plot. NVAR=ALL uses all variables that you specify in the VAR statement. By default, NVAR=5.

RESOLUTION=*n*

specifies the number of bins to use for the X and Y axes when you create plots. By default, RESOLUTION=50.

SCATTER

creates a scatter plot matrix of variables that you specify in the VAR statement. The maximum number of variables that you can display in the scatter plot matrix is 10.

TAIL | **CHI**

creates tail dependence plots (chi plots). If you specify this option together with the UNPACK option, PROC CCOPULA displays a chi plot of each applicable pair of distinct variables that you specify in the VAR statement. If you specify this option without the UNPACK option, PROC CCOPULA displays a scatter plot matrix; the lower triangular section of the matrix shows regular scatter plots between distinct pairs of variables that are specified in the VAR statement, and the upper triangular section of the matrix shows chi plots of corresponding pairs of variables.

UNPACK | **UNPACKPANEL**

creates scatter plots of pairs of variables. If you specify this option, PROC CCOPULA displays a scatter plot of each applicable pair of distinct variables that you specify in the VAR statement.

You can also specify the following *specific-plot-options*:

DATATYPE=UNIFORM

shows the data by using uniformly distributed margins. Plotting data by using the empirical marginal distribution specified in the DATA= data table is not supported in this release.

DATATYPE=ORIGINAL | UNIFORM | BOTH

specifies the data type to be plotted. DATATYPE=ORIGINAL plots the data transformed into the marginal distributions specified in the DATA= option in the PROC CCOPULA statement. DATATYPE=UNIFORM shows the data with a uniform marginal distribution. DATATYPE=BOTH plots both the original and uniform data types.

NONE

suppresses all plots.

RESTORE=SAS-item-store

specifies the input item store that contains the results of fitting a copula. The final estimates, correlations, and other properties of the model that are preserved in the RESTORE= item store are used to define the simulation. The DEFINE and VAR statements are ignored if this option is specified.

SEED=integer

specifies the seed for generating random numbers for the simulation. If you do not specify the seed, then the seed is generated by reading the time of day from the computer's clock.

TOLERANCE=value

specifies the tolerance allowed for the simulation.

VAR Statement

VAR *variables* ;

The VAR statement specifies the variable names in the input data table that is specified by the DATA= option in the PROC CCOPULA statement. The subset of variables in the data table is used for the copula models in the FIT statement. If there is no input data table, the VAR statement creates the list of variable names for the SIMULATE statement.

VIEWSTORE Statement

VIEWSTORE / *options* ;

The VIEWSTORE statement enables you to print various reports that describe the model fitting information that is preserved in an item store. The item store must have been created using the STORE= option in the FIT statement. You can specify the following *options*:

ALL

prints the entire contents of the item store.

BYVARVALUES

prints the values of the BY-group variables that are used to fit the model.

CORRELATIONS

prints the correlations matrices.

FINALESTIMATES

prints the final parameter estimates.

FITMODELSUMMARY

prints the fit model summary.

INITIALESTIMATES

prints the initial parameter estimates.

INSTORE=SAS-item-store

specifies the item store that you want to view. If you omit this option, and if you use a FIT statement to specify a STORE= item store, then the STORE= item store that is specified in the FIT statement is used as the INSTORE= item store.

MINIMAL

prints only the fit model summary and the solution.

MODELDEFINITION

prints the statements that define the model.

NONE

suppresses all reports.

OPTIMIZERSETTINGS

prints the optimizer settings that are used to fit the model.

Details: CCOPULA Procedure

Sklar's Theorem

The copula models are tools for studying the dependence structure of multivariate distributions. The usual joint distribution function contains the information both about the marginal behavior of the individual random variables and about the dependence structure between the variables. The copula is introduced to decouple the marginal properties of the random variables and the dependence structures. An m -dimensional *copula* is a joint distribution function on $[0, 1]^m$, where all marginal distributions are standard uniform. The common notation for a copula is $C(u_1, \dots, u_m)$.

The Sklar (1959) theorem shows the importance of copulas in modeling multivariate distributions. The first part of the theorem states that a copula can be derived from any joint distribution functions, and the second part asserts the opposite: that any copula can be combined with any set of marginal distributions to result in a multivariate distribution function. The theorem follows:

- Let F be a joint distribution function, and let $F_j, j = 1, \dots, m$, be the marginal distributions. Then there exists a copula $C : [0, 1]^m \rightarrow [0, 1]$ such that

$$F(x_1, \dots, x_m) = C(F_1(x_1), \dots, F_m(x_m))$$

for all $x_1, \dots, x_m$ in $[-\infty, \infty]$. Moreover, if the margins are continuous, then C is unique; otherwise C is uniquely determined on $\text{Ran} F_1 \times \dots \times \text{Ran} F_m$, where $\text{Ran} F_j = F_j([-\infty, \infty])$ is the range of F_j .

- The converse is also true. That is, if C is a copula and $F_1, \dots, F_m$ are univariate distribution functions, then the multivariate function that is defined in the preceding equation is a joint distribution function with marginal distributions $F_j, j = 1, \dots, m$.

Dependence Measures

There are three basic types of dependence measures: linear correlation, rank correlation, and tail dependence. Linear correlation is given by

$$\rho \equiv \text{corr}(X, Y) = \frac{\text{cov}(X, Y)}{\sqrt{\text{var}(X)}\sqrt{\text{var}(Y)}}$$

The linear correlation coefficient contains very limited information about the joint properties of the variables. A well-known property is that zero correlation does not imply independence, whereas independence implies zero correlation. In addition, there are distinct bivariate distributions that have the same marginal distribution and the same correlation coefficient. These results suggest that caution must be used in interpreting the linear correlation.

Another statistical measure of dependence is rank correlation, which is nonparametric. For example, Kendall's tau is the covariance between the sign statistics $X_1 - \tilde{X}_1$ and $X_2 - \tilde{X}_2$, where $(\tilde{X}_1, \tilde{X}_2)$ is an independent copy of (X_1, X_2) :

$$\rho_\tau \equiv E[\text{sign}(X_1 - \tilde{X}_1)(X_2 - \tilde{X}_2)]$$

The sign function (sometimes written as sgn) is defined as

$$\text{sign}(x) = \begin{cases} -1 & \text{if } x \leq 0 \\ 0 & \text{if } x = 0 \\ 1 & \text{if } x \geq 0 \end{cases}$$

Spearman's rho is the correlation between the transformed random variables:

$$\rho_S(X_1, X_2) \equiv \rho(F_1(X_1), F_2(X_2))$$

The variables are transformed by their distribution functions so that the transformed variables are uniformly distributed on $[0, 1]$. The rank correlations depend only on the copula of the random variables and are indifferent to the marginal distributions. Like linear correlation, rank correlation has its limitations. In particular, different copulas result in the same rank correlation.

A third measure, tail dependence, focuses on only part of the joint properties between the variables. Tail dependence measures the dependence when both variables have extreme values. Formally, they can be defined as the conditional probabilities of quantile exceedances. There are two types of tail dependence:

- Upper tail dependence is defined as

$$\lambda_u(X_1, X_2) \equiv \lim_{q \rightarrow 1^-} P(X_2 > F_2^{-1}(q) | X_1 > F_1^{-1}(q))$$

when the limit exists and $\lambda_u \in [0, 1]$. Here F_j^{-1} is the quantile function (that is, the inverse of the CDF).

- Lower tail dependence is defined symmetrically.

Tail dependence is hard to detect by looking at a scatter plot of realizations of two random variables. One graphical way to detect tail dependence between two variables is by creating the chi plot of those two variables. The chi plot, as defined in Fisher and Switzer (2001), has characteristic patterns that depend on the dependence structure between the variables. The chi plot of the random variables X and Y is a scatter plot of the pairs (λ_i, χ_i) for each data point (x_i, y_i) . λ_i is a measure of the distance of the data point (x_i, y_i) from the center of the data as measured by the median values of (x_i, y_i) , and χ_i is a correlation coefficient between dichotomized values of X and Y . A positive λ_i means that x_i and y_i are either both large with respect to their median values or both small. A negative λ_i means that x_i or y_i is large with respect to its median and that the other value is small. Signs of tail dependence manifest as clusters of points that are significantly far from the χ axis around λ values of ± 1 . If X and Y are uncorrelated, the χ values cluster around the λ axis.

A Kendall plot enables you to compare the multivariate cumulative distribution function (CDF) for observed data to the CDF for a reference distribution. The Kendall plot is a multidimensional analog to the Q-Q plot that is used to compare distributions in one dimension. In both Q-Q plots and Kendall plots, you visually assess the similarity between the distributions of two random samples, A and B , by creating a scatter plot of the ordered values of A versus B . In the unpacked version of Kendall plots output by the CCOPULA procedure, three reference curves are displayed in addition to the observed, or simulated data. The horizontal reference curve is a Kendall plot for variables with a correlation of -1. The diagonal curve is Kendall plot for an uncorrelated bivariate uniform distribution. The arced curve is a Kendall plot for variables with a correlation of +1.

Data Processing and Fitting

Before you can fit a copula, you must transform the data into pseudo-uniform data. If you specify the MARGINALS=UNIFORM option, then it is assumed that the data are already in the proper form, so the required transformation is the trivial identity transformation. However, if you specify MARGINALS=EMPIRICAL (or if you omit the MARGINALS= option), then the transformation is nontrivial.

For relatively small data tables, each observation in the original input data table can be transformed into a pseudo-uniform observation by using a simple value-comparison algorithm. In this case, the initial estimates of the parameters in t copulas and Archimedean copulas can be derived by computing a Kendall correlations matrix on the basis of the transformed data.

However, for larger data tables, the simple value-comparison algorithm becomes computationally impractical as a means of transforming the original data into pseudo-uniform data. Thus, a data binning algorithm is used to transform the original data into pseudo-uniform data. After the data have been transformed in this way, it can still be computationally impractical to compute a Kendall correlations matrix directly from the data, because the algorithm for deriving the Kendall correlations matrix requires a pairwise comparison of every

pair of observations. Therefore, after the data have been transformed via binning, a Pearson correlations matrix is computed on the basis of the transformed data, and then a Kendall correlations matrix is derived from the Pearson correlations matrix by applying an analytical formula. Then the initial estimates for the parameters in the t copulas and Archimedean copulas are derived from the Kendall correlations matrix.

Adaptive Approximation of Marginal Distributions

Simple binning into fixed-width intervals of each variable's empirical data can lead to a poor approximation of distributions for variables that have highly nonsmooth distributions. For smaller data tables, fixed-interval bins can be an inefficient representation of the empirical distributions because many bins are empty.

To accommodate variables that have a wide range of empirical distributions, PROC CCOPULA uses an adaptive binning algorithm to generate an approximation of each variable's cumulative distribution function (CDF). The following steps summarize how an approximate CDF is computed for each variable:

1. A partitioning of the equal-width intervals specified in the REFINERES= option of the FIT statement between the minimum and maximum values is created so that each value falls into one interval.
2. The number of values that fall within each interval is counted.
3. Each interval is assigned a weight on the basis of its count.
4. Each interval is subdivided into a number of subintervals proportional to its weight so that the total number of new subdivisions across all intervals equals the value specified in the REFINERES= option of the FIT statement.
5. The process of subdividing intervals is repeated starting at step 2 until either the weight of each interval falls below a threshold value or the algorithm has run the number of times specified in the MAXITERS= option of the FIT statement.

After a final partitioning with counts has been created, the count that is associated with each interval is modified to include the cumulative counts for all smaller intervals.

The CDF for a particular value is computed by interpolating the counts between the endpoints of its interval, by using the method that you specify in the INTERP= option.

Two alternative approaches are available for counting the number of observations in step 2 of the approximation algorithm. When you specify ALG=BIN, the interval counts are computed by locating the interval associated with each observation and incrementing that interval's count. When you specify ALG=SORT, all the observations are stored in memory and sorted to make the assignment of observations to intervals faster in step 2.

The adaptive algorithm executes its steps in parallel across all available threads and machines except for step 5, in which the partitioning available on each thread must be merged and shared with all other threads.

Normal Copula

Let $u_j \sim U(0, 1)$ for $j = 1, \dots, m$, where $U(0, 1)$ represents the uniform distribution on the $[0, 1]$ interval. Let Σ be the correlations matrix, where $m(m-1)/2$ parameters satisfy the positive semidefiniteness constraint. The normal copula can be written as

$$C_{\Sigma}(u_1, u_2, \dots, u_m) = \Phi_{\Sigma}(\Phi^{-1}(u_1), \dots, \Phi^{-1}(u_m))$$

where Φ is the distribution function of a standard normal random variable and Φ_{Σ} is the m -variate standard normal distribution with mean vector 0 and covariance matrix Σ . That is, the distribution Φ_{Σ} is $N_m(0, \Sigma)$.

Simulation

For the normal copula, the input of the simulation is the correlations matrix Σ . The normal copula can be simulated by the following steps, in which $\mathbf{U} = (U_1, \dots, U_m)$ denotes one random draw from the copula:

1. Generate a multivariate normal vector $\mathbf{Z} \sim N(0, \Sigma)$, where Σ is an m -dimensional correlations matrix.
2. Transform the vector $\mathbf{Z}$ into $\mathbf{U} = (\Phi(Z_1), \dots, \Phi(Z_m))^T$, where Φ is the distribution function of univariate standard normal.

The first step can be achieved by Cholesky decomposition of the correlations matrix $\Sigma = LL^T$, where L is a lower triangular matrix with positive elements on the diagonal. If $\tilde{\mathbf{Z}} \sim N(0, I)$, then $L\tilde{\mathbf{Z}} \sim N(0, \Sigma)$.

Fitting

To fit a normal copula is to estimate the covariance matrix Σ from an input sample data table. Given a random sample $\mathbf{u}_i = (u_{i,1}, \dots, u_{i,m})^T$ where $i = 1, \dots, n$, the log-likelihood function is

$$\begin{aligned} \log L(\Sigma; \mathbf{u}_1, \dots, \mathbf{u}_n) \\ = \sum_{t=1}^n \log f_{\Sigma}(\Phi^{-1}(u_{t,1}), \dots, \Phi^{-1}(u_{t,m})) - \sum_{t=1}^n \sum_{j=1}^m \log \phi(\Phi^{-1}(u_{t,j})) \end{aligned}$$

Here f_{Σ} is the joint density of the multivariate normal with mean zero and variance Σ , and ϕ is the univariate density of the standard normal distribution. Note that the second term is not related to the parameters Σ and, therefore, can be ignored during the optimization. The restriction that Σ is a correlations matrix is very inconvenient, and it is common practice to circumvent this problem by first assuming that Σ has the covariance form. Therefore, Σ can be estimated by

$$\hat{\Sigma} = \frac{1}{n} \sum_{i=1}^n \xi_i \xi_i^T$$

where

$$\xi_i = (\Phi^{-1}(u_{i,1}), \Phi^{-1}(u_{i,2}), \dots, \Phi^{-1}(u_{i,m}))^T$$

This estimate is consistent with the form of a covariance matrix but not necessarily with the form of a correlations matrix. The approximation to the original MLE problem can be obtained using the normalizing operator defined as follows:

$$\Delta(\Sigma) = \text{diag}(\sigma_{11}^{1/2}, \dots, \sigma_{mm}^{1/2})$$

$$\mathcal{P}(\Sigma) = (\Delta(\Sigma))^{-1} \Sigma (\Delta(\Sigma))^{-1}$$

Student's t copula

Let $\Theta = \{(\nu, \Sigma) : \nu \in (1, \infty), \Sigma \in \mathbb{R}^{m \times m}\}$, and let t_ν be a univariate t distribution with ν degrees of freedom.

The Student's t copula can be written as

$$C_\Theta(u_1, u_2, \dots, u_m) = t_{\nu, \Sigma} \left(t_\nu^{-1}(u_1), t_\nu^{-1}(u_2), \dots, t_\nu^{-1}(u_m) \right)$$

where $t_{\nu, \Sigma}$ is the multivariate Student's t distribution that has a correlations matrix Σ with ν degrees of freedom.

Simulation

The input parameters for the simulation are (ν, Σ) . The t copula can be simulated by the following steps:

1. Generate a multivariate vector $\mathbf{X} \sim t_m(\nu, 0, \Sigma)$ that follows the centered t distribution with ν degrees of freedom and correlations matrix Σ .
2. Transform the vector $\mathbf{X}$ into $\mathbf{U} = (t_\nu(X_1), \dots, t_\nu(X_m))^T$, where t_ν is the distribution function of univariate t distribution with ν degrees of freedom.

To simulate centered multivariate t random variables, you can use the property that $\mathbf{X} \sim t_m(\nu, 0, \Sigma)$ if $\mathbf{X} = \sqrt{\nu/s} \mathbf{Z}$, where $\mathbf{Z} \sim N(0, \Sigma)$ and the univariate random variable $s \sim \chi_\nu^2$.

Fitting

To fit a t copula is to estimate the covariance matrix Σ and degrees of freedom ν from given multivariate data. Given a random sample $\mathbf{u}_i = (u_{i,1}, \dots, u_{i,m})^T$, $i = 1, \dots, n$ that has uniform marginal distributions, the log likelihood is

$$\log L(\nu, \Sigma; u_{i,1}, \dots, u_{i,m})$$

$$= \sum_{i=1}^n \log g_{\nu, \Sigma}(t_\nu^{-1}(u_{i,1}), \dots, t_\nu^{-1}(u_{i,m})) - \sum_{i=1}^n \sum_{j=1}^m \log g_\nu(t_\nu^{-1}(u_{i,j}))$$

where ν denotes the degrees of freedom of the t copula, $g_{\nu, \Sigma}$ denotes the joint density function of the centered multivariate t distribution with parameters (ν, Σ) , t_ν is the distribution function of a univariate t distribution with ν degrees of freedom, Σ is a correlations matrix, and g_ν is the density function of univariate t distribution with ν degrees of freedom.

The log likelihood can be maximized with respect to the parameters $\theta = (\nu, \Sigma) \in \Theta$ using numerical optimization. If you allow the parameters in Σ to be such that Σ is symmetric and with ones on the diagonal, then the MLE estimate for Σ might not be positive semidefinite. In that case, you need to apply the adjustment to convert the estimated matrix to positive semidefinite, as shown by McNeil, Frey, and Embrechts (2005), Algorithm 5.55.

When the dimension of the data m increases, the numerical optimization quickly becomes infeasible. It is common practice to estimate the correlations matrix Σ by calibration using Kendall's tau. Then, using this fixed Σ , the single parameter ν can be estimated by MLE. By proposition 5.37 in McNeil, Frey, and Embrechts (2005),

$$\rho_{\tau}(U_i, U_j) = \frac{2}{\pi} \arcsin \rho_{ij}$$

where ρ_{τ} is the Kendall's tau and ρ_{ij} is the off-diagonal elements of the correlations matrix Σ of the t copula. Therefore, an estimate for the correlation is

$$\hat{\rho}_{ij} = \sin \left(\frac{1}{2} \pi \hat{\rho}_{i,j}^{\tau} \right)$$

where $\hat{\rho}$ and $\hat{\rho}^{\tau}$ are the estimates of the sample correlations matrix and Kendall's tau, respectively. However, it is possible that the estimate of the correlations matrix $\hat{\Sigma}$ is not positive definite. In this case, there is a standard procedure that uses the eigenvalue decomposition to transform the correlations matrix into one that is positive definite. Let Σ be a symmetric matrix with ones on the diagonal, with off-diagonal entries in $[-1, 1]$. If Σ is not positive semidefinite, use Algorithm 5.55 from McNeil, Frey, and Embrechts (2005):

1. Compute the eigenvalue decomposition $\Sigma = EDE^T$, where D is a diagonal matrix that contains all the eigenvalues and E is an orthogonal matrix that contains the eigenvectors.
2. Construct a diagonal matrix $\tilde{D}$ by replacing all negative eigenvalues in D by a small value $\delta > 0$.
3. Compute $\tilde{\Sigma} = E\tilde{D}E^T$, which is positive definite but not necessarily a correlations matrix.
4. Apply the normalizing operator $\mathcal{P}$ on the matrix $\tilde{\Sigma}$ to obtain the correlations matrix desired.

The log-likelihood function and its gradient function for a single observation are listed as follows, where $\xi = (\xi_1, \dots, \xi_m)$, with $\xi_j = t_{\nu}^{-1}(u_j)$, and g is the derivative of the log Γ function:

$$\begin{aligned}
l = \log(c) &= -\frac{1}{2} \log(|\Sigma|) + \log \Gamma\left(\frac{\nu+m}{2}\right) + (m-1) \log \Gamma\left(\frac{\nu}{2}\right) - m \log \Gamma\left(\frac{\nu+1}{2}\right) \\
&\quad - \frac{\nu+m}{2} \log(1 + \zeta^T \Sigma^{-1} \zeta / \nu) + \frac{\nu+1}{2} \sum_{j=1}^m \log\left(1 + \frac{\zeta_j^2}{\nu}\right) \\
\frac{\partial l}{\partial \nu} &= \frac{1}{2} g\left(\frac{\nu+m}{2}\right) + \frac{m-1}{2} g\left(\frac{\nu}{2}\right) - \frac{m}{2} g\left(\frac{\nu+1}{2}\right) \\
&\quad - \frac{1}{2} \log(1 + \zeta^T \Sigma^{-1} \zeta / \nu) + \frac{\nu+m}{2\nu^2} \frac{\zeta^T \Sigma^{-1} \zeta}{1 + \zeta^T \Sigma^{-1} \zeta / \nu} \\
&\quad + \frac{1}{2} \sum_{j=1}^m \log(1 + \zeta_j^2 / \nu) - \frac{\nu+1}{2\nu^2} \sum_{j=1}^m \frac{\zeta_j^2}{1 + \zeta_j^2 / \nu} \\
&\quad - \frac{(\nu+m)}{\nu} \frac{\zeta^T \Sigma^{-1} (d\zeta/d\nu)}{1 + \zeta^T \Sigma^{-1} \zeta / \nu} + \frac{\nu+1}{\nu} \sum_{j=1}^m \frac{\zeta_j (d\zeta_j/d\nu)}{1 + \zeta_j^2 / \nu}
\end{aligned}$$

The derivative of the likelihood with respect to the correlations matrix Σ follows:

$$\begin{aligned}
\frac{\partial l}{\partial \Sigma} &= -\frac{1}{2} (\Sigma^{-1})^T + \frac{\nu+m}{2} \frac{\Sigma^{-T} \zeta \zeta^T \Sigma^{-T} / \nu}{1 + \zeta^T \Sigma^{-1} \zeta / \nu} \\
&= -\frac{1}{2} (\Sigma^{-1})^T + \frac{\nu+m}{2} \frac{\Sigma^{-T} \zeta \zeta^T \Sigma^{-T}}{\nu + \zeta^T \Sigma^{-1} \zeta}
\end{aligned}$$

Archimedean Copulas

Overview of Archimedean Copulas

Let function $\phi : [0, 1] \rightarrow [0, \infty)$ be a strict Archimedean copula generator function, and suppose that its inverse ϕ^{-1} is completely monotonic on $[0, \infty)$. A strict generator is a decreasing function $\phi : [0, 1] \rightarrow [0, \infty)$ that satisfies $\phi(0) = \infty$ and $\phi(1) = 0$. A decreasing function $f(t) : [a, b] \rightarrow (-\infty, \infty)$ is completely monotonic if it satisfies

$$(-1)^k \frac{d^k}{dt^k} f(t) \geq 0, k \in \mathbb{N}, t \in (a, b)$$

An Archimedean copula is defined as follows:

$$C(u_1, u_2, \dots, u_m) = \phi^{-1}\left(\phi(u_1) + \dots + \phi(u_m)\right)$$

The Archimedean copulas available in the CCOPULA procedure are the Clayton copula, the Frank copula, and the Gumbel copula.

Clayton Copula

Let the generator function $\phi(u) = \theta^{-1} (u^{-\theta} - 1)$. A Clayton copula is defined as

$$C_\theta(u_1, u_2, \dots, u_m) = \left[\sum_{i=1}^m u_i^{-\theta} - m + 1 \right]^{-1/\theta}$$

where $\theta > 0$.

Frank Copula

Let the generator function be

$$\phi(u) = -\log \left[\frac{\exp(-\theta u) - 1}{\exp(-\theta) - 1} \right]$$

A Frank copula is defined as

$$C_\theta(u_1, u_2, \dots, u_m) = \frac{1}{\theta} \log \left\{ 1 + \frac{\prod_{i=1}^m [\exp(-\theta u_i) - 1]}{[\exp(-\theta) - 1]^{m-1}} \right\}$$

where $\theta \in (-\infty, \infty) \setminus \{0\}$ for $m = 2$ and $\theta > 0$ for $m \geq 3$.

Gumbel Copula

Let the generator function $\phi(u) = (-\log u)^\theta$. A Gumbel copula is defined as

$$C_\theta(u_1, u_2, \dots, u_m) = \exp \left\{ - \left[\sum_{i=1}^m (-\log u_i)^\theta \right]^{1/\theta} \right\}$$

where $\theta > 1$.

Simulation

Suppose that the generator of the Archimedean copula is ϕ . Then the simulation method that uses a Laplace-Stieltjes transformation of the distribution function is given by Marshall and Olkin (1988), where $\tilde{F}(t) = \int_0^\infty e^{-tx} dF(x)$:

1. Generate a random variable V that has the distribution function F such that $\tilde{F}(t) = \phi^{-1}(t)$.
2. Draw samples from the independent uniform random variables $X_1, \dots, X_m$.
3. Return $U = (\tilde{F}(-\log(X_1)/V), \dots, \tilde{F}(-\log(X_m)/V))^T$.

The Laplace-Stieltjes transformations are as follows:

- For the Clayton copula, $\tilde{F} = (1 + t)^{-1/\theta}$, and the distribution function F is associated with a gamma random variable that has a shape parameter of θ^{-1} and a scale parameter of 1.

- For the Gumbel copula, $\tilde{F} = \exp(-t^{1/\theta})$, and F is the distribution function of the stable variable $\text{St}(\theta^{-1}, 1, \gamma, 0)$, where $\gamma = [\cos(\pi/(2\theta))]^\theta$.
- For the Frank copula where $\theta > 0$, $\tilde{F} = -\log\{1 - \exp(-t)[1 - \exp(-\theta)]\}/\theta$, and F is a discrete probability function $P(V = k) = (1 - \exp(-\theta))^k/(k\theta)$. This probability function is related to a logarithmic random variable that has a parameter value of $1 - e^{-\theta}$.

For more information about simulating a random variable from a stable distribution, see Theorem 1.19 in Nolan (2010). For more information about simulating a random variable from a logarithmic series, see Chapter 10.5 in Devroye (1986).

For a Frank copula where $m = 2$ and $\theta < 0$, the simulation can be done through conditional distributions as follows:

1 Draw independent v_1, v_2 from a uniform distribution.

2 Let $u_1 = v_1$.

3 Let $u_2 = -\frac{1}{\theta} \log \left(1 + \frac{v_2(1-e^{-\theta})}{v_2(e^{-\theta v_1}-1)-e^{-\theta v_1}} \right)$.

Fitting

One method to estimate the parameters is to calibrate with Kendall's tau. The relation between the parameter θ and Kendall's tau is summarized in Table 8.2 for the three Archimedean copulas.

Table 8.2 Calibration Using Kendall's Tau

Copula Type	τ	Formula for θ
Clayton	$\theta/(\theta + 2)$	$2\tau/(1 - \tau)$
Gumbel	$1 - 1/\theta$	$1/(1 - \tau)$
Frank	$1 - 4\theta^{-1}(1 - D_1(\theta))$	No closed form

In Table 8.2, $D_1(\theta) = \theta^{-1} \int_0^\theta t/(\exp(t) - 1)dt$ for $\theta > 0$, and $D_1(\theta) = D_1(\theta) + 0.5\theta$ for $\theta < 0$. In addition, for the Frank copula, the formula for θ has no closed form. The numerical algorithm for root finding can be used to invert the function $\tau(\theta)$ to obtain θ as a function of τ .

Alternatively, you can use the MLE or CMLE method to estimate the parameter θ given the data $\mathbf{u} = \{u_{i,j}\}$ and $i = 1, \dots, n, j = 1, \dots, m$. The log-likelihood function for each type of Archimedean copula is provided in the following sections.

Fitting the Clayton Copula

For the Clayton copula, the log-likelihood function is as follows (Cherubini, Luciano, and Vecchiato 2004, Chapter 7):

$$l = n \left[m \log(\theta) + \log \left(\Gamma \left(\frac{1}{\theta} + m \right) \right) - \log \left(\Gamma \left(\frac{1}{\theta} \right) \right) \right] - (\theta + 1) \sum_{i,j} \log u_{ij} \\ - \left(\frac{1}{\theta} + m \right) \sum_i \log \left(\sum_j u_{ij}^{-\theta} - m + 1 \right)$$

Let $g(\cdot)$ be the derivative of $\log(\Gamma(\cdot))$. Then the first-order derivative is

$$\frac{dl}{d\theta} = n \left[\frac{m}{\theta} + g \left(\frac{1}{\theta} + m \right) \frac{-1}{\theta^2} - g \left(\frac{1}{\theta} \right) \frac{-1}{\theta^2} \right] \\ - \sum_{i,j} \log(u_{ij}) + \frac{1}{\theta^2} \sum_i \log \left(\sum_j u_{ij}^{-\theta} - m + 1 \right) \\ - \left(\frac{1}{\theta} + m \right) \sum_i \frac{-\sum_j u_{ij}^{-\theta} \log(u_{ij})}{\sum_j u_{ij}^{-\theta} - m + 1}$$

The second-order derivative is

$$\frac{d^2l}{d\theta^2} = n \left\{ \frac{-m}{\theta^2} + g' \left(\frac{1}{\theta} + m \right) \frac{1}{\theta^4} + g \left(\frac{1}{\theta} + m \right) \frac{2}{\theta^3} - g' \left(\frac{1}{\theta} \right) \frac{1}{\theta^4} - g \left(\frac{1}{\theta} \right) \frac{2}{\theta^3} \right\} \\ - \frac{2}{\theta^3} \sum_i \log \left(\sum_j u_{ij}^{-\theta} - m + 1 \right) \\ + \frac{2}{\theta^2} \sum_i \frac{-\sum_j u_{ij}^{-\theta} \log u_{ij}}{\sum_j u_{ij}^{-\theta} - m + 1} \\ - \left(\frac{1}{\theta} + m \right) \sum_i \left\{ \frac{\sum_j u_{ij}^{-\theta} (\log u_{ij})^2}{\sum_j u_{ij}^{-\theta} - m + 1} - \left(\frac{\sum_j u_{ij}^{-\theta} \log u_{ij}}{\sum_j u_{ij}^{-\theta} - m + 1} \right)^2 \right\}$$

Fitting the Gumbel Copula

A different parameterization $\alpha = \theta^{-1}$ is used for the following part, which is related to the fitting of the Gumbel copula. For the Gumbel copula, you need to compute $\phi^{-1(m)}$. It turns out that for $k = 1, 2, \dots, m$,

$$\phi^{-1(k)}(u) = (-1)^k \alpha \exp(-u^\alpha) u^{-k+\alpha} \Psi_{k-1}(u^\alpha)$$

where Ψ_{k-1} is a function that is described later. The copula density is given by

$$c = \phi^{-1(m)}(x) \prod_k \phi'(u_k) \\ = (-1)^m \alpha \exp(-x^\alpha) x^{-k+\alpha} \Psi_{m-1}(x^\alpha) \prod_k \phi'(u_k) \\ = (-1)^m f_1 f_2 f_3 f_4 f_5$$

where $x = \sum_k \phi(u_k)$, $f_1 = \alpha$, $f_2 = \exp(-x^\alpha)$, $f_3 = x^{-k+\alpha}$, $f_4 = \Psi_{m-1}(x^\alpha)$, and $f_5 = (-1)^m \prod_k \phi'(u_k)$.

The log density is

$$\begin{aligned} l &= \log(c) \\ &= \log(f_1) + \log(f_2) + \log(f_3) + \log(f_4) + \log((-1)^m f_5) \end{aligned}$$

Now the first-order derivative of the log density has the decomposition

$$\frac{dl}{d\alpha} = \frac{1}{c} \frac{dc}{d\alpha} = \sum_{j=1}^4 \frac{1}{f_j} \frac{df_j}{d\alpha} + \frac{d \sum_k \log(-\phi'(u_k))}{d\alpha}$$

Some of the terms are given by

$$\begin{aligned} \frac{1}{f_1} \frac{df_1}{d\alpha} &= \frac{1}{\alpha} \\ \frac{1}{f_2} \frac{df_2}{d\alpha} &= -x^\alpha \log(x) - \alpha x^{\alpha-1} \frac{dx}{d\alpha} \\ \frac{1}{f_3} \frac{df_3}{d\alpha} &= \log(x) + (-k + \alpha) x^{-1} \frac{dx}{d\alpha} \end{aligned}$$

where

$$\frac{dx}{d\alpha} = \sum (-\log u_k)^{1/\alpha} \log(-\log u_k) \left(\frac{-1}{\alpha^2} \right)$$

The last term in the derivative of the $dl/d\alpha$ is

$$\begin{aligned} \log(-\phi'(u_k)) &= \log\left(\frac{1}{\alpha} (-\log u_k)^{\frac{1}{\alpha}-1} \frac{1}{u_k}\right) \\ &= -\log \alpha - \log(u_k) + \left(\frac{1}{\alpha} - 1\right) \log(-\log(u_k)) \\ \frac{d \sum_k \log(-\phi'(u_k))}{d\alpha} &= \sum_{k=1}^m -\frac{1}{\alpha} - \frac{1}{\alpha^2} \log(-\log(u_k)) \\ &= -\frac{m}{\alpha} - \frac{1}{\alpha^2} \sum_{k=1}^m \log(-\log(u_k)) \end{aligned}$$

Now the only remaining term is f_4 , which is related to Ψ_{m-1} . Wu, Valdez, and Sherris (2007) show that $\Psi_k(x)$ satisfies a recursive equation

$$\Psi_k(x) = [\alpha(x-1) + k] \Psi_{k-1}(x) - \alpha x \Psi'_{k-1}(x)$$

with $\Psi_0(x) = 1$.

The preceding equation implies that $\Psi_{k-1}(x)$ is a polynomial of x and therefore can be represented as

$$\Psi_{k-1}(x) = \sum_{j=0}^{k-1} a_j(k-1, \alpha) x^j$$

In addition, its coefficient, denoted by $a_j(k-1, \alpha)$, is a polynomial of α . For simplicity, use the notation $a_j(\alpha) \equiv a_j(m-1, \alpha)$. Therefore,

$$f_4 = \Psi_{m-1}(x^\alpha) = \sum_{j=0}^{m-1} a_j(\alpha) x^{j\alpha}$$

$$\begin{aligned} \frac{df_4}{d\alpha} &= \frac{d\Psi_{m-1}(x^\alpha)}{d\alpha} \\ &= \sum_{j=0}^{m-1} \left[\frac{da_j(\alpha)}{d\alpha} x^{j\alpha} + a_j(\alpha) x^{j\alpha} \log(x) j + a_j(\alpha) (j\alpha) x^{j\alpha-1} \frac{dx}{d\alpha} \right] \end{aligned}$$

Fitting the Frank Copula

For the Frank copula,

$$\phi^{-1(k)}(u) = -\frac{1}{\theta} \Psi_{k-1} \left((1 + e^{-u}(e^{-\theta} - 1))^{-1} \right)$$

When $\theta > 0$, a Frank copula has a probability density function

$$\begin{aligned} c &= \varphi^{-1(m)}(x) \prod_k \varphi'(u_k) \\ &= \frac{-1}{\theta} \Psi_{m-1} \left(\frac{1}{1 + e^{-x}(e^{-\theta} - 1)} \right) \prod_k \varphi'(u_k) \end{aligned}$$

where $x = \sum_k \varphi(u_k)$.

The log likelihood is

$$\log c = -\log(\theta) + \log \left(\Psi_{m-1} \left(\frac{1}{1 + e^{-x}(e^{-\theta} - 1)} \right) \right) + \sum \log(\varphi'(u_k))$$

Denote

$$y = \frac{1}{1 + e^{-x}(e^{-\theta} - 1)}$$

Then the derivative of the log likelihood is

$$\frac{d \log c}{d\theta} = -\frac{1}{\theta} + \frac{1}{\Psi_{m-1}(y)} \frac{d\Psi_{m-1}}{d\theta} + \sum_k \frac{1}{\varphi'(u_k)} \frac{d\varphi'(u_k)}{d\theta}$$

The term in the last summation is

$$\frac{1}{\varphi'(u_k)} \frac{d\varphi'(u_k)}{d\theta} = \frac{1}{\theta(1 - e^{\theta u_k})} [1 - e^{\theta u_k} + \theta u_k e^{\theta u_k}]$$

The function Ψ_{m-1} satisfies a recursive relation

$$\Psi_k(x) = x(x-1)\Psi'_{k-1}(x)$$

with $\Psi_0(x) = x - 1$. Note that Ψ_{m-1} is a polynomial whose coefficients do not depend on θ ; therefore,

$$\begin{aligned} \frac{d\Psi_{m-1}}{d\theta} &= \frac{d\Psi_{m-1}}{dy} \frac{dy}{d\theta} \\ &= \frac{d\Psi_{m-1}}{dy} \left[\frac{dy}{d\theta} + \frac{dy}{dx} \frac{dx}{d\theta} \right] \\ &= \frac{d\Psi_{m-1}}{dy} \left[\frac{e^{-x}e^{-\theta}}{[1 + e^{-x}(e^{-\theta} - 1)]^2} + \frac{e^{-x}(e^{-\theta} - 1)}{[1 + e^{-x}(e^{-\theta} - 1)]^2} \frac{dx}{d\theta} \right] \end{aligned}$$

where

$$\begin{aligned} \frac{dx}{d\theta} &= \sum_k \frac{d\varphi(u_k)}{d\theta} = \sum_k \left[-\frac{u_k e^{-\theta u_k}}{1 - e^{-\theta u_k}} + \frac{e^{-\theta}}{1 - e^{-\theta}} \right] \\ &= \sum_k \left[-\frac{u_k}{e^{\theta u_k} - 1} + \frac{1}{e^{\theta} - 1} \right] \end{aligned}$$

For the case of $m = 2$ and $\theta < 0$, the bivariate density is

$$\log c = \log(\theta(1 - e^{-\theta})) - \theta(u_1 + u_2) - \log((1 - e^{-\theta} - (1 - e^{-\theta u_1})(1 - e^{-\theta u_2}))^2)$$

Canonical Maximum Likelihood Estimation (CMLE)

In the canonical maximum likelihood estimation (CMLE) method, it is assumed that the sample data $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{im})^\top$, where $i = 1, \dots, n$, have been transformed into uniform variates $\hat{\mathbf{u}}_i = (\hat{u}_{i1}, \dots, \hat{u}_{im})$, $i = 1, \dots, n$. One commonly used transformation is the nonparametric estimation of the CDF of the marginal distributions, which is closely related to empirical CDF,

$$\hat{u}_{i,j} = \hat{F}_{j,n}(x_{i,j})$$

where

$$\hat{F}_{j,n}(x) = \frac{1}{n+1} \sum_{i=1}^n I_{[x_{i,j} \leq x]}$$

The transformed data $\hat{u}_{i,j}$ are used as if they had uniform marginal distributions; hence, they are called pseudo-samples. The function $\hat{F}_{j,n}$ is different from the standard empirical CDF in the scalar $1/(n+1)$,

which is to ensure that the transformed data cannot be on the boundary of the unit interval $[0, 1]$. It is clear that

$$\hat{u}_{i,j} = \frac{1}{n+1} \text{rank}(x_{i,j})$$

where $\text{rank}(x_{i,j})$ is the rank among $i = 1, \dots, n$ in increasing order.

Let $c(u_1, u_2, \dots, u_m; \theta)$ be the density function of a copula $C(u_1, u_2, \dots, u_m; \theta)$, and let θ be the parameter vector to be estimated. The parameter θ is estimated by maximum likelihood:

$$\hat{\theta} = \arg \max_{\theta \in \Theta} \sum_{i=1}^n \log c(\hat{u}_{i1}, \dots, \hat{u}_{im}; \theta)$$

Exact Maximum Likelihood Estimation (MLE)

Suppose that the marginal distributions of vector elements $\mathbf{x}_i = (x_{i1}, x_{i2}, \dots, x_{im})^\top$, where $i = 1, \dots, n$, are already known to be uniform. Then the parameter θ is estimated by exact maximum likelihood:

$$\hat{\theta} = \arg \max_{\theta \in \Theta} \sum_{i=1}^n \log c(x_{i1}, x_{i2}, \dots, x_{im}; \theta)$$

Calibration Estimation

Instead of fitting the whole distribution as in MLE methods, you can directly use empirical estimates of distribution parameters. The unknown parameter that you want to estimate can be obtained by calibration that uses Kendall's tau. There is a one-to-one map between the parameter of interest and Kendall's tau. Therefore, after you estimate Kendall's tau, you can use the map to compute the parameter value. For example, the parameter matrix Σ in a t copula and the parameter θ in Archimedean copulas can be estimated in this manner. The most frequently used estimator of Kendall's tau is the rank correlation coefficient:

$$\hat{\rho}_\tau(X_i, X_j) = \left(\frac{n}{2} \right)^{-1} \sum_{1 \leq t < s \leq n} \text{sign}((x_{t,i} - x_{s,i})(x_{t,j} - x_{s,j}))$$

The preceding formula is analogous to its population counterpart,

$$\rho_\tau(X_i, X_j) = E[\text{sign}((X_i - \tilde{X}_i)(X_j - \tilde{X}_j))]$$

where $(\tilde{X}_i, \tilde{X}_j)$ has the same distribution but is independent of (X_i, X_j) .

For Archimedean multivariate copulas, there is only one parameter to estimate, τ (or its function θ), although for m variables there are $m(m-1)/2$ unique pairwise correlation coefficients. Denote the map from ρ_τ to θ by $\theta = \hat{\theta}(\rho_\tau)$. To aggregate the map, take a simple arithmetic average:

$$\hat{\theta} = \frac{2}{m(m-1)} \sum_{1 \leq i < j \leq m} \hat{\theta}[\hat{\rho}_\tau(X_i, X_j)]$$

Nonlinear Optimization Options

PROC CCOPULA uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. In the PROC CCOPULA statement, you can specify nonlinear optimization options that are then passed to the NLO subsystem. For a list of all the nonlinear optimization options, see *SAS/ETS User's Guide*.

Displayed Output

PROC CCOPULA produces the displayed output that is described in the following sections.

Optimization Start and Resulting Parameter Estimates

If you specify the ITPRINT option in the PROC CCOPULA statement, PROC CCOPULA displays two tables, “Optimization Start Parameter Estimates” and “Optimization Results Parameter Estimates.” Each table contains the following information for each model parameter:

- parameter number
- parameter name
- parameter estimate
- gradient of the objective function at the initial parameter values

In addition to this information, the “Optimization Start Parameter Estimates” table contains the following columns:

- lower-bound constraint
- upper-bound constraint

The value of the objective function at the parameter values is displayed below each table.

Iteration History for Parameter Estimates

If you specify the ITPRINT option in the PROC CCOPULA statement, PROC CCOPULA displays a table that contains the following information for each iteration. Note that some information is specific to the model-fitting method that you choose (for example, Newton-Raphson, trust region, or quasi-Newton method).

- iteration number
- number of restarts since the fitting began
- number of function calls
- number of active constraints at the current solution

- value of the objective function (-1 times the log-likelihood value) at the current solution
- change in the objective function from the previous iteration
- value of the maximum absolute gradient element
- step size (for Newton-Raphson and quasi-Newton methods)
- slope of the current search direction (for Newton-Raphson and quasi-Newton methods)
- lambda (for trust region method)
- radius value at the current iteration (for trust region method)

Model Fit Summary

The “Model Fit Summary” table contains the following information:

- number of observations used
- number of missing values in the data table, if any
- data table name
- type of model that was fit
- log-likelihood value at the solution
- maximum absolute gradient at the solution
- number of iterations
- optimization method
- value of Akaike’s information criterion (AIC) at the solution (a smaller value indicates better fit)
- value of Schwarz Bayesian criterion (SBC) at the solution (a smaller value indicates better fit)

Below the “Model Fit Summary” table is a statement about whether the algorithm successfully converged.

Parameter Estimates

The “Parameter Estimates” table contains the estimates of the model parameters. For the normal copula, this table is not displayed because the only parameters are in the correlations matrix, which is displayed in the “Pearson Correlations Matrix” table. For the t copula, the parameter is the number of degrees of freedom; in the table it is called “DF.” For Archimedean copulas such as Clayton, Frank, and Gumbel, the parameter is called “theta.”

Pearson Correlations Matrix

The “Pearson Correlations Matrix” table contains the estimates of the model Pearson correlations matrix. This table is displayed only for the normal and t copulas. Row and column names come from the list of variables that are defined in the VAR statement.

Kendall Correlations Matrix

The “Kendall Correlations Matrix” table contains the estimates of the model Kendall correlations matrix. This table is displayed only for the normal and t copulas. Row and column names come from the list of variables that are defined in the VAR statement.

Spearman Correlations Matrix

The “Spearman Correlations Matrix” table contains the estimates of the model Spearman correlations matrix. This table is displayed only for the normal copula. Row and column names come from the list of variables that are defined in the VAR statement.

OUTPSEUDO= and OUTUNIFORM= Data Tables

The number of columns and the names of columns in the OUTPSEUDO= and OUTUNIFORM= data tables match the number and names of the variables in the VAR statement.

ODS Table Names

PROC CCOPULA assigns a name to each table that it creates. You can use these names to denote the table when you use the Output Delivery System (ODS) to select tables and create output data tables. These table names are listed in [Table 8.3](#).

Table 8.3 ODS Tables Produced by PROC CCOPULA

Table Name	Description	Option
ODS Tables Created by the FIT Statement		
ConvergenceStatus	Convergence status	Default
PearsonCorrelations	Pearson correlations matrix estimates	Default with elliptical copulas
KendallCorrelations	Kendall correlations matrix estimates	Default with elliptical copulas
SpearmanCorrelations	Spearman correlations matrix estimates	Default with normal copula
ParameterEstimates	Parameter estimates	Default
ODS Tables Created by the PRINTTIMING Option		
TimingDetails	Detailed summary of time used for all phases of execution	PRINTTIMING=(DETAILS)

Table 8.3 *continued*

Table Name	Description	Option
TimingSummary	Summary of time used for main phases of execution	PRINTTIMING
ODS Table Created by the SIMULATE Statement		
SimulateModelSummary	Summary of simulation	Default

ODS Graph Names

PROC CCOPULA assigns a name to each graph that it creates by using ODS. You can use these names to selectively reference the graphs. The names are listed in [Table 8.4](#).

Table 8.4 ODS Graphics Produced by PROC CCOPULA

ODS Graph Name	Plot Description	PLOTS= Option

Examples: CCOPULA Procedure

Example 8.1: Simulating Default Times

Suppose that the correlations structure that is required for a normal copula function is already given. For example, it can be estimated from the historic data on default times in some set of industries, but this stage is not within the scope of this example. The correlations structure is saved in a SAS data set called `inparm`. The following statements and their output in [Output 8.1.1](#) show that the correlation parameter for Y1 and Y2 is set at 0.8:

```
proc print data = inparm;
run;
```

Output 8.1.1 Pearson Correlations Matrix

Obs	Y1	Y2
1	1.0	0.8
2	0.8	1.0

Then you use PROC CCOPULA as follows to simulate the data. The VAR statement specifies the list of variables to contain simulated data. The DEFINE statement assigns the name COP and specifies a normal copula that reads the correlations matrix from the `inparm` data table.

The SIMULATE statement refers to the COP label that is defined in the VAR statement and specifies some options: the NDRAWS= option specifies a sample size, the SEED= option specifies 1234 as the random number generator seed, and the OUTUNIFORM=NORMAL_UNIFDATA option names the output data table for the result of simulation in uniforms.

```
/* simulate the data from bivariate normal copula */
proc ccopula ;
  var Y1-Y2;
  define cop normal (corr=mylib.inparm);
  simulate cop /
    ndraws      = 1000000
    seed        = 1234
    outuniform  = mylib.normal_unifdata;
run;
```

The following DATA step transforms the variables from zero-one uniformly distributed to nonnegative exponentially distributed with parameter 0.5. Three indicator variables are added to the data table. SURVIVE1 and SURVIVE2 have a value of 1 if a respective company has remained in business for more than three years. DEFAULT has a value of 1 if neither company survived for more than three years.

```
/* default time has exponential marginal distribution with parameter 0.5 */
data default;
  set mylib.normal_unifdata;
  array arr{2} Y1-Y2;
  array time{2} time1-time2;
  array surv{2} survive1-survive2;
  lambda = 0.5;
  do i=1 to 2;
    time[i] = -log(1-arr[i])/lambda;
    surv[i] = 0;
    if (time[i] >3) then surv[i]=1;
  end;
  default = 0;
  if (time1 <=3) && (time2 <=3) then default = 1;
run;
```

The first analysis step is to look at correlations between survival times of two companies. This step is performed by using the following CORR procedure statements:

```
proc corr data = default pearson kendall;
  var time1 time2;
run;
```

The output is shown in [Output 8.1.2](#).

Output 8.1.2 Default Time Descriptive Statistics and Correlations

The CORR Procedure

2 Variables: time1 time2

Simple Statistics						
Variable	N	Mean	Std Dev	Median	Minimum	Maximum
time1	1000000	2.00023	1.99883	1.38633	3.85293E-6	24.18938
time2	1000000	1.99897	1.99965	1.38476	6.43006E-6	25.85567

Pearson Correlation Coefficients, N = 1000000
Prob > |r| under H0: Rho=0

	time1	time2
time1	1.00000	0.77046 <.0001
time2	0.77046 <.0001	1.00000

Output 8.1.2 *continued*

Kendall Tau b Correlation Coefficients, N = 1000000 Prob > tau under H0: Tau=0		
	time1	time2
time1	1.00000	0.59046 <.0001
time2	0.59046 <.0001	1.00000

Output 8.1.2 shows some descriptive statistics and two measures of correlation: Pearson and Kendall. Both of these measures indicate high and statistically significant dependence between life spans of two companies.

The second and final step is to empirically estimate the default probabilities of two companies. This is done using the FREQ procedure as follows:

```
proc freq data=default;
    table default survive1-survive2;
run;
```

The results are shown in Output 8.1.3.

Output 8.1.3 Probabilities of Default**The FREQ Procedure**

default	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	298431	29.84	298431	29.84
1	701569	70.16	1000000	100.00

survive1	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	776594	77.66	776594	77.66
1	223406	22.34	1000000	100.00

survive2	Frequency	Percent	Cumulative Frequency	Cumulative Percent
0	777292	77.73	777292	77.73
1	222708	22.27	1000000	100.00

Output 8.1.3 shows that the empirical default probabilities are 77.66% and 77.73%. If you assume that these companies are independent, the probability estimate that both companies will default during the period of three years is $0.7766 \times 0.7773 = 0.6037$ (60.37%). If you compare this naive estimate to the higher actual joint default probability of 70.16%, you see that if you neglected the correlation between the two companies, you underestimate the probability of default.

Example 8.2: Copula Analysis of Stock Returns

In this example, the correlations of daily returns on the large capital stocks Microsoft, Coca-Cola, IBM, Duke Energy, and British Petroleum are modeled using a t copula. To model the correlations, these companies' stock prices are first converted into returns by using the following DATA step:

```
data allreturns;
    format date MMDDYY10.;
    input date:MMDDYY10. price_ibm price_msft price_bp price_ko price_duk;
    ret_msft = price_msft/lag(price_msft)-1;
    ret_ko   = price_ko/lag(price_ko)-1;
    ret_ibm  = price_ibm/lag(price_ibm)-1;
    ret_duk  = price_duk/lag(price_duk)-1;
    ret_bp   = price_bp/lag(price_bp)-1;
    if ret_msft ^= .;
    keep date ret_ibm ret_msft ret_bp ret_ko ret_duk;
datalines;
01/02/2008    99.91    33.48    62.78    56.91    17.13
01/03/2008   100.11    33.62    63.98    57.50    17.19
01/04/2008    96.52    32.68    63.05    57.61    17.18
01/07/2008    95.49    32.90    64.18    58.97    17.62

... more lines ...
```

The stock return data can then be visualized and used to estimate the parameters of a t copula by using the following code:

```
/* Copula estimation and simulation of returns */
proc ccopula data = mylib.allreturns;
    var ret_ibm ret_msft ret_bp ret_ko ret_duk;
    * fit t-copula to stock returns;
    fit T / marginals = empirical
           method     = MLE
           plots = (datatype = both);
run;

proc ccopula;
    var x1-x5;
    define t t(df=5);
    simulate t / ndraws=603 seed=100 outuniform=mylib.copuniform plots;
run;

proc ccopula data=mylib.copuniform;
    var x1-x5;
    fit T / marginals = uniform
           method     = MLE
           plots = (datatype = uniform);
run;
```

The output from these statements is shown in [Output 8.2.1](#).

Output 8.2.1 Copula Estimation**The CCOPULA Procedure**

Model Fit Summary				
Number of Observations	603			
Data Set	ALLRETURNS			
Copula Type	T			
Fit Method	MLE			
Marginals	Empirical			
Empirical Approximation	Adaptive Binning			
Adaptive Refinement Resolution	1000			
Adaptive Interpolation Method	Linear			
Number of Adaptive Iterations	4			
Log Likelihood	634.6931			
Maximum Absolute Gradient	1.596E-7			
Number of Iterations	7			
Optimization Method	Newton-Raphson			
AIC	-1247.39			
SBC	-1198.97			

Parameter Estimates				
Parameter	Estimate	Standard Error	t Value	Approx Pr > t
DF	3.659299	0.320474	11.42	<.0001

Pearson Correlations Matrix					
Variable	ret_ibm	ret_msft	ret_bp	ret_ko	ret_duk
ret_ibm	1.0000	0.6415	0.5195	0.5004	0.5023
ret_msft	0.6415	1.0000	0.5137	0.4935	0.4388
ret_bp	0.5195	0.5137	1.0000	0.4063	0.4278
ret_ko	0.5004	0.4935	0.4063	1.0000	0.5266
ret_duk	0.5023	0.4388	0.4278	0.5266	1.0000

The first table in [Output 8.2.1](#), “Model Fit Summary,” provides some general description of copula model estimation. The second table, “Parameter Estimates,” provides point estimates and inference about copula parameters. In this example, the only parameter in this table is the number of degrees of freedom in the multivariate t distribution. The last table, “Correlation Matrix,” contains estimates of copula model parameters.

The graphical output from the preceding statements is shown in [Output 8.2.2](#) and [Output 8.2.3](#).

Output 8.2.2 Original Data

Output 8.2.3 Original Data Transformed into Uniform Marginals

Note that in [Output 8.2.2](#), the most elliptical scatter plot, which is between IBM and Microsoft, indicates the strongest dependence. Similarly, in [Output 8.2.3](#), graphs that are denser along the diagonal indicate the same thing.

Example 8.3: Copula Analysis of S&P 500 Sectors

This example analyzes the dependencies among the market sectors in the S&P 500 index. The S&P 500 index consists of 11 sectors: Information Technology, Health Care, Financials, Consumer Discretionary, Communication Services, Industrials, Consumer Staples, Energy, Utilities, Real Estate, and Materials. This analysis considers daily returns for these sectors that have been corrected for stock splits and dividend payments over the years 1999 to 2020.

To facilitate visualization of the return data, this analysis is limited to the Utilities, Consumer Discretionary, Industrials, and Financials sectors. The following code fits a t copula and performs a simulation of the estimated t copula:

```
/* PROC CCOPULA visualization of sector returns */
proc ccopula data=mylib.sectret;
  var utilities discretionary industrial financial;
  fit t / marginals=empirical plots(tail kendall)=(datatype=uniform)
        store=mylib.sectstor;
  simulate / seed=1 ndraws=5635 outuniform=mylib.outuniform
        plots(tail kendall)=(datatype=uniform);
run;
```

[Output 8.3.1](#) compares the tail plots of the actual return data to plots of the simulated data. Both plots show similar patterns for the dependencies among the various sectors. In particular, the Utilities sector appears to have a consistently low correlation with the other sectors for returns near the mean and for both the high and low extreme values. For the other three sectors, higher correlations are apparent among the returns. Based on the correlation and tail plots in [Output 8.3.1](#), you would be likely to conclude that the estimated t copula represents the dependencies among returns well.

Output 8.3.1 Actual (Upper) and Simulated (Lower) Tail Plots

Output 8.3.1 *continued*

Output 8.3.2 compares the Kendall plots of the actual return data to plots of the simulated data. The Kendall plots for these sectors show that the t copula models the range of returns well. Plots of both the observed and simulated data relative to a uniform bivariate distributions show similar patterns.

Output 8.3.2 Actual (Upper) and Simulated (Lower) Kendall Plots

Output 8.3.2 continued

Overview: CESM Procedure

The CESM procedure generates forecasts by using exponential smoothing models with optimized smoothing weights for one or more time series. Time series data have observations that are equally spaced by a specific time interval (for example, monthly or weekly).

PROC CESM can also generate these forecasts for transactional data, whose observations are not spaced with respect to any particular time interval. The procedure accumulates transactional data on the basis of a specified (or default) time interval to form a time series prior to modeling and forecasting. Typical examples of transactional data are internet, inventory, sales, and other similar data.

For typical time series, you can use the following smoothing models: simple, double, linear, damped trend, seasonal, and Winters method (additive or multiplicative). In addition, transformed versions of the following models are provided: log, square root, logistic, and Box-Cox.

The CESM procedure writes the following to output data tables: the time series that are extrapolated by the forecasts, the series summary statistics, the forecasts and confidence limits, and the parameter estimates.

PROC CESM requires SAS Cloud Analytic Services (CAS) in order to run, and it does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;  
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the `CASHOST` and `CASPORT` of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the `TERMINATE` option in the `CAS` statement as follows:

```
cas mysess terminate;
```

For more information about the `CAS` and `LIBNAME` statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CESM Procedure

The CESM procedure is simple to use and does not require in-depth knowledge of forecasting methods. It can provide results in output data tables. The examples in this section are more fully illustrated in “[Examples: CESM Procedure](#)” on page 358.

The following statements generate forecasts for every numeric variable in the time series in the input data table `mylib.sales`, which contains sales data that are recorded monthly:

```
proc cesm data=mylib.sales outfor=mylib.nextyear;  
  id date interval=month;  
  forecast _numeric_ / lead=12;  
run;
```

The `DATA=` option specifies `mylib.sales` as the input data table, and the `OUTFOR=` option requests that the forecast be output to the `mylib.nextYear` table. The `ID` statement specifies the variable that represents time (`Date`) and specifies that the time series data are spaced monthly. The `_NUMERIC_` specification in the `FORECAST` statement requests that every numeric variable in the input data table be forecast, and the `LEAD=12` options requests that the time series be forecast for the next 12 months.

The following statements show how you can forecast data that contain transactional variables that are not recorded at any specific frequency:

```
proc cesm data=mylib.websites outfor=mylib.nextweek;  
  id time interval=dtday accumulate=total;  
  forecast boats cars planes / lead=7;  
run;
```

The `DATA=` option specifies the input data table `mylib.websites`, which contains three variables (`Boats`, `Cars`, and `Planes`) in internet data that are recorded at no particular time interval. The `OUTFOR=` option requests that forecasts for the total daily values be recorded in the `mylib.nextWeek` data table. The `ID` statement specifies `Time` (which records the time of a website hit) as the variable that represents time and requests that the data be accumulated into a daily time series. The `FORECAST` statement requests that forecasts for the `Boats`, `Cars`, and `Planes` variables be generated. The `LEAD=7` option requests that forecasts be generated for the next seven days. Because the `METHOD=` option is not specified in the `FORECAST` statement, `PROC CESM` fits each series by selecting the best exponential smoothing model (which is the default model) according to the default criterion of root mean square error (RMSE).

Syntax: CESM Procedure

The following statements are available in the CESM procedure:

```
PROC CESM options ;
  BY variables ;
  ID variable INTERVAL= interval < options > ;
  FORECAST variable-list / < options > ;
```

Functional Summary

Table 9.1 summarizes the statements and options that are available in the CESM procedure.

Table 9.1 Functional Summary

Description	Statement	Option
Statements		
Specifies data tables and options	PROC CESM	
Specifies BY-group processing	BY	
Specifies variables to forecast	FORECAST	
Specifies the time ID variable	ID	
Data Set Options		
Specifies the input data table	PROC CESM	DATA=
Specifies the output data table	PROC CESM	OUT=
Specifies the parameter output data table	PROC CESM	OUTEST=
Specifies the forecast output data table	PROC CESM	OUTFOR=
Specify statistics output data table	PROC CESM	OUTSTAT=
Specifies the summary output data table	PROC CESM	OUTSUM=
Accumulation and Seasonality Options		
Specifies the accumulation frequency	ID	INTERVAL=
Specifies the length of seasonal cycle	PROC CESM	SEASONALITY=
Specifies the interval alignment	ID	ALIGN=
Specifies the starting time ID value	ID	START=
Specifies the ending time ID value	ID	END=
Specifies the accumulation statistic	ID, FORECAST	ACCUMULATE=
Specifies how to interpret missing values	ID, FORECAST	SETMISSING=
Forecasting Horizon, Holdback Options		
Specifies the data to hold back	FORECAST	BACK=
Specifies the forecast horizon or lead	FORECAST	LEAD=
Forecasting Model Options		
Specifies the confidence limit width	FORECAST	ALPHA=
Specifies the model selection criterion	FORECAST	CRITERION=

Description	Statement	Option
Specifies the forecast model	FORECAST	METHOD=
Specifies the median forecasts	FORECAST	MEDIAN
Specifies the model transformation	FORECAST	TRANSFORM=
Miscellaneous Options		
Specifies the time ID format	ID	FORMAT=
Specifies the method for trimming the data in the BY groups	ID	TRIMID=

The following sections describe the PROC CESM statement and then describe the other statements in alphabetical order.

PROC CESM Statement

PROC CESM *options* ;

You can specify the following *options*:

DATA=*libref.data-table*

names the input data table for PROC CESM to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

data-table specifies the name of the input data table.

OUT=*libref.data-table*

names the output data table to contain the forecasts of the variables that are specified in subsequent FORECAST statements. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the DATA= option and the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

The *variable* that is specified in the ID statement is also included in the output data set. The values are accumulated based on the ACCUMULATE= option. The OUT= data table is particularly useful in extending the independent variables.

OUTEST=libref.data-table

names the output data table to contain the model parameter estimates and the associated test statistics and probability values. The OUTEST= data table is useful for evaluating the significance of the model parameters and for understanding the model dynamics.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

OUTFOR=libref.data-table

names the output data table to contain the forecast time series components (actual, predicted, lower confidence limit, upper confidence limit, prediction error, and prediction standard error). The OUTFOR= data table is useful for displaying the forecasts in tabular or graphical form.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

OUTSTAT=libref.data-table

names the output data table to contain the statistics of fit (or goodness-of-fit statistics). The OUTSTAT= data table is useful for evaluating how well the model fits the series. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

OUTSUM=libref.data-table

names the output data table to contain the summary statistics and the forecast summation. The summary statistics are based on the accumulated time series when the ACCUMULATE= or SETMISSING= option is specified in the FORECAST statement. The OUTSUM= data table is useful when large numbers of series are forecasted and a summary of the results is needed.

libref.data-table is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 338.

SEASONALITY=number

specifies the length of the seasonal cycle. For example, SEASONALITY=3 means that every group of three observations forms a seasonal cycle. This option is applicable only for seasonal forecasting models. By default, the length of the seasonal cycle is 1 (no seasonality) or the length that is implied by the INTERVAL= option in the ID statement. For example, INTERVAL=MONTH implies that the length of the seasonal cycle is 12.

BY Statement

BY *variables* ;

You can use a BY statement to obtain separate dummy variable definitions for groups of observations that are defined by the BY variables.

FORECAST Statement

FORECAST *variable-list* / < *options* > ;

The FORECAST statement lists the numeric variables in the input data table whose accumulated values represent time series to be modeled and forecast. (The input data table is specified in the DATA= option in the PROC CESM statement.)

You must specify a *variable-list* that contains one or more numeric variables. For more information about the *variable-list*, see the section “SAS Variable Lists” in *SAS Programmers Guide: Essentials*.

You can specify any number of FORECAST statements, but you cannot specify the same variable in more than one of them.

You can specify the following *options* to specify which forecast model to use:

ACCUMULATE=*option*

specifies how to accumulate the data table observations within each time period for the variables in the *variable-list*. If the ACCUMULATE= option is not specified in the FORECAST statement, accumulation is determined by the ACCUMULATE= option in the ID statement. Use the ACCUMULATE= option with multiple FORECAST statements when you want different accumulation specifications for different variables. For more information, see the [ACCUMULATE=](#) option in the ID statement.

ALPHA=*number*

specifies the significance level to use in computing the confidence limits of the forecast, where *number* must be between 0 and 1. By default, ALPHA=0.05, which produces 95% confidence intervals.

BACK=*n*

specifies the number of observations before the end of the data where the multistep forecasts are to begin. By default, BACK=0.

CRITERION=*criterion*

specifies the model selection criterion (statistic of fit) to use to select from several candidate models. The default is CRITERION=RMSE. The following statistics of fit are provided:

SSE	sum of square error
MSE	mean squared error
RMSE	root mean squared error
UMSE	unbiased mean squared error
URMSE	unbiased root mean squared error
MAXPE	maximum percent error

MINPE	minimum percent error
MPE	mean percent error
MAPE	mean absolute percent error
MDAPE	median percent error
GMAPE	geometric mean percent error
MAPES	mean absolute error percent of standard deviation
MDAPES	median absolute error percent of standard deviation
GMAPES	geometric mean absolute error percent of standard deviation
MINPPE	minimum predictive percent error
MAXPPE	maximum predictive percent error
MPPE	mean predictive percent error
MAPPE	symmetric mean absolute predictive percent error
MDAPPE	median predictive percent error
GMAPPE	geometric mean predictive percent error
MINSPE	minimum symmetric percent error
MAXSPE	maximum symmetric percent error
MSPE	mean symmetric percent error
SMAPE	symmetric mean absolute percent error
MDASPE	median symmetric percent error
GMASPE	geometric mean symmetric percent error
MINRE	minimum relative error
MAXRE	maximum relative error
MRE	mean relative error
MRAE	mean relative absolute error
MDRAE	median relative absolute error
GMRAE	geometric mean relative absolute error
MAXERR	maximum error
MINERR	minimum error
ME	mean error
MAE	mean absolute error
MASE	mean absolute scaled error
RSQUARE	R-square
ADJRSQ	adjusted R-square
AADJRSQ	Amemiya's adjusted R-square
RWRSQ	random walk R-square

AIC	Akaike information criterion
AICC	Akaike information corrected criterion
SBC	Schwarz Bayesian information criterion
APC	Amemiya's prediction criterion

LEAD=*n*

specifies the number of periods ahead to forecast (the forecast lead or horizon).

The value *n* is not relative to the last nonmissing observation of a particular series, but is instead relative to the BACK= option specification to the last observation in the input data table or the accumulated series. Thus, if a series has missing values at the end, the actual number of forecasts computed for that series is greater than *n*.

By default, LEAD=0.

MEDIAN

estimates the median forecast values and uses those values for forecasting. (By default, PROC CESM uses mean values for forecasting.) If you do not specify the TRANSFORM= option, no transformation is applied to the time series, so the mean and median forecast values are identical.

METHOD=*model-name*

specifies the forecasting model to use to forecast the time series. You can specify the following forecasting *model-names*:

ADDWINTERS	requests the Winters additive method.
BEST	requests the best candidate smoothing model among the SIMPLE, LINEAR, DAMPTREND, SEASONAL, ADDWINTERS, or WINTERS methods.
BESTN	requests the best candidate nonseasonal smoothing model among the SIMPLE, LINEAR, or DAMPTREND methods.
BESTS	requests the best candidate seasonal smoothing model among the SEASONAL, ADDWINTERS, or WINTERS methods.
DAMPTREND	requests damped trend exponential smoothing.
DOUBLE	requests second-order exponential smoothing.
LINEAR	requests linear (Holt) exponential smoothing.
MULTSEASONAL	requests multiplicative seasonal exponential smoothing.
SEASONAL	requests additive seasonal exponential smoothing.
SIMPLE	requests simple (single) exponential smoothing.
WINTERS	requests Winters multiplicative method.

By default, METHOD=BEST.

SETMISSING=*option* | *number*

specifies how to assign missing values (either input or accumulated) in the accumulated time series for variables in the *variable-list*. If the SETMISSING= option is not specified in the FORECAST statement, missing values are set according to the value of the SETMISSING= option in the ID statement. For more information, see the SETMISSING= option in the ID statement.

TRANSFORM=*option*

specifies the time series transformation to be applied to the input or accumulated time series. You can specify the following values for *option*:

AUTO	automatically chooses between NONE and LOG on the basis of the model selection criteria.
BOXCOX (<i>n</i>)	performs Box-Cox transformation with parameter number (<i>n</i>), where <i>n</i> must be between –5 and 5.
LOG	performs logarithmic transformation.
LOGISTIC	performs logistic transformation.
NONE	performs no transformation.
SQRT	performs square-root transformation.

By default, TRANSFORM=NONE.

When the TRANSFORM= option is specified, the time series must be strictly positive. After the time series is transformed, the model parameters are estimated by using the transformed series. The forecasts of the transformed series are then computed, and finally the transformed series forecasts are inverse-transformed. The inverse transform produces either mean or median forecasts depending on whether the MEDIAN option is specified. For more information, see the sections “[Transformations](#)” on page 352 and “[Inverse Transformations](#)” on page 353.

ID Statement

ID *variable* **INTERVAL=***interval* < *options* > ;

The ID statement names a numeric *variable* that identifies observations in the input and output data tables. The values of the ID *variable* are assumed to be SAS date or datetime values. In addition, the ID statement specifies (in the INTERVAL= option) the frequency that is associated with the time series. The *options* also specify how to accumulate the observations and how to align the time ID values to form the time series to be forecast. The specified information affects all variables that are specified in subsequent FORECAST statements. If an ID statement is not specified, the observation number (with respect to the BY group) is used as the time ID.

You must specify the following argument:

INTERVAL=*interval*

specifies the frequency of the input time series or of the time series to be accumulated from the input data. For example, if the input data table consists of quarterly observations, then **INTERVAL=QTR** should be used. If the **SEASONALITY=** option is not specified, the length of the seasonal cycle is implied by the **INTERVAL=** option. For example, **INTERVAL=QTR** implies a seasonal cycle of length 4. If the **ACCUMULATE=** option is also specified, the **INTERVAL=** option determines the time periods for the accumulation of observations.

The basic intervals are **YEAR**, **SEMIYEAR**, **QTR**, **MONTH**, **SEMIMONTH**, **TENDAY**, **WEEK**, **WEEKDAY**, **DAY**, **HOURL**, **MINUTE**, and **SECOND**. For more information about the intervals that can be specified, see the chapter “Date Intervals, Formats, and Functions” in *SAS/ETS User’s Guide*.

You can also specify the following *options*:

ACCUMULATE=*option*

specifies how to accumulate the data table observations within each time period. The frequency (width of each time interval) is specified in the **INTERVAL=** option. The **ID variable** contains the time ID values. Each value of the time ID *variable* value corresponds to a specific time period. The accumulated values form the time series, which is used in subsequent model fitting and forecasting.

The **ACCUMULATE=** option is particularly useful when there are gaps in the input data or when there are multiple input observations that coincide with a particular time period (for example, transactional data). The **EXPAND** procedure in *SAS/ETS User’s Guide* offers additional frequency conversions and transformations that can also be useful in creating a time series.

You can specify the following *options* to determine how to accumulate the observations within each time period based on the **ID variable** and the frequency that is specified in the **INTERVAL=** option:

TOTAL SUM	accumulates observations based on the total sum of their values.
AVERAGE AVG	accumulates observations based on the average of their values.
MINIMUM MIN	accumulates observations based on the minimum of their values.
MAXIMUM MAX	accumulates observations based on the maximum of their values.
N	accumulates observations based on the number of nonmissing observations.
NMISS	accumulates observations based on the number of missing observations.
STDDEV STD	accumulates observations based on the standard deviation of their values.
CSS	accumulates observations based on the corrected sum of squares of their values.
USS	accumulates observations based on the uncorrected sum of squares of their values.

By default, **ACCUMULATE=TOTAL**.

If the **ACCUMULATE=** option is specified, the **SETMISSING=** option is useful for specifying how to treat accumulated missing values. If missing values should be interpreted as 0, then you should specify **SETMISSING=0**. For more information about accumulation, see the section “[Accumulation](#)” on page 350.

ALIGN=option

controls the alignment of SAS date or datetime values that are used to identify the time period of output observations. Although any date or datetime value within the time period can identify the time period, this option requests that the representative date or datetime for the time period be calculated as the beginning date or datetime of the time period, the ending date or datetime of the time period, or the middle date or datetime of the time period. In addition to aligning the time ID values consistently for observations that are supplied by the user, this option specifies the method for calculating the time ID values for observations in the forecast and backcast time periods, which often are not supplied by the user. You can specify the following *options*:

- BEGINNING | BEG | B** represents each time period by using the beginning SAS date or datetime value of the time period.
- ENDING | END | E** represents each time period by using the ending SAS date or datetime value of the time period.
- MIDDLE | MID | M** represents each time period by using the middle SAS date or datetime value of the time period. The middle is calculated as the average of the beginning and ending values.

By default, ALIGN=BEGINNING.

END=date | datetime

specifies a SAS date or datetime literal value that represents the end of the data. If the value of the last time ID variable is less than the END= value, the series is extended with missing values. If the value of the last time ID variable is greater than the END= value, the series is truncated. For example, **END='1jan2008'D** requests that data for time periods after the first of January 2008 not be used. The option **END='&sysdate'D** uses the automatic macro variable SYSDATE to extend or truncate the series to the current date. You can use this option and the START= option to ensure that data that are associated with each BY group contain the same number of observations.

FORMAT=format

specifies the SAS format for the time ID values. If the FORMAT= option is not specified, the default format is implied by the INTERVAL= option.

SETMISSING=n | option

specifies how to interpret missing values (either actual or accumulated) in the accumulated time series. You can specify either a number (*n*) or an *option* to determine how to interpret missing values:

- n* interprets a missing value as having the value *n*. You can specify any number for *n*, but not a missing value. If a missing value indicates a 0 value, specify SETMISSING=0. You typically use SETMISSING=0 for transactional data because no recorded data usually implies no activity.
- MISSING** interprets a missing value as a missing value. Use this option if a missing value indicates an unknown value.
- AVERAGE | AVG** interprets a missing value as the average value of all accumulated nonmissing values in the span of the series.
- MINIMUM | MIN** interprets a missing value as the minimum value of all accumulated nonmissing values in the span of the series.

MEDIAN MED	interprets a missing value as the median value of all accumulated nonmissing values in the span of the series.
MAXIMUM MAX	interprets a missing value as the maximum value of all accumulated nonmissing values in the span of the series.
FIRST	interprets a missing value as the first nonmissing value of all accumulated nonmissing values in the span of the series.
LAST	interprets a missing value as the last nonmissing value of all accumulated nonmissing values in the span of the series.
PREVIOUS PREV	interprets a missing value as the previous period's accumulated nonmissing value. Missing values at the beginning of the accumulated series remain missing.
NEXT	interprets a missing value as the next period's accumulated nonmissing value. Missing values at the end of the accumulated series remain missing.

By default, SETMISSING=MISSING.

START=*date* | *datetime*

specifies a SAS date or datetime literal value that represents the beginning of the data. If the value of the first time ID variable is greater than the START= value, the series is prefixed with missing values. If the value of the first time ID variable is less than the START= value, the series is truncated. You can use this option and the END= option to ensure that data that are associated with each BY group contain the same number of observations.

TRIMID=*method*

specifies the method for trimming the data in the BY groups. The output time ID variable span that is calculated by the *method* is dependent on the input time ID variable span, irrespective of missing values of the time series variables. Depending on the *method* and the input time ID variable data, leading or trailing missing values can be added to the time series variables.

After the output time ID variable span is calculated by the *method*, the ending value of the output time ID variable is recalculated according to the value of the LEAD= option in the FORECAST statement (if the LEAD= option is specified).

You can specify one of the following *methods*:

NONE	uses the same starting and ending values of the output time ID variable for all BY groups. The span of the output time ID variable includes all values that are input as a time ID value for all BY groups. The time series variables are extended with leading or trailing missing values as required.
LEFT	uses the identifying date for the first time period that is input for the BY group as the starting value of the output time ID variable for each BY group. The time series values in each BY group are not extended with leading missing values. The ending value of the time ID variable is the same for all BY groups. The time series variables are extended with trailing missing values as required.
RIGHT	uses the identifying date for the last time period that is input for the BY group as the ending value of the output time ID variable for each BY group. The time series values in each BY group are not extended with trailing missing values. The starting value of the time ID

variable is the same for all BY groups. The time series variables are extended with leading missing values as required.

BOTH uses the span of the input time ID variable for the BY group as the span of the output time ID variable for each BY group. The time series values in each BY group are not extended with leading or trailing missing values.

By default, TRIMID=NONE.

Details: CESM Procedure

You can use the CESM procedure to forecast both time series data and transactional data. If the data are transactional, then the procedure must first accumulate the data into a time series before it can forecast them. [Table 9.2](#) shows the sequential steps that the procedure uses to produce forecasts; the options that control each step and the statements where those options can be specified are shown in the third and fourth columns, respectively.

Table 9.2 CESM Processing Steps and Control Options

Step	Operation	Option	Statements
1	Accumulation	ACCUMULATE=	ID, FORECAST
2	Missing value interpretation	SETMISSING=	ID, FORECAST
3	Transformations	TRANSFORM=	FORECAST
4	Parameter estimation	METHOD=	FORECAST
5	Forecasting	METHOD=, LEAD=	FORECAST
6	Inverse transformation	TRANSFORM, MEDIAN	FORECAST

Each of the steps shown in [Table 9.2](#) is described in the following sections.

Accumulation

If the ACCUMULATE= option is specified in the ID statement, data table observations are accumulated within each time period. The frequency (width of each time interval) is specified in the INTERVAL= option in the ID statement, and the variable that is specified in the ID statement contains the time ID values. Each time ID value corresponds to a specific time period. Accumulation is particularly useful when the input data table contains transactional data, whose observations are not spaced with respect to any particular time interval. The accumulated values form the time series that is used in subsequent analyses by the CESM procedure.

For example, suppose a data table contains the following observations:

```
19MAR1999    10
19MAR1999    30
11MAY1999    50
12MAY1999    20
```

23MAY1999 20

If the INTERVAL=MONTH option is specified in the ID statement, all the preceding observations fall within three time periods: March 1999, April 1999, and May 1999. The observations are accumulated within each time period as follows.

- If the ACCUMULATE=NONE option is specified, an error is generated because the ID variable values are not equally spaced with respect to the specified frequency (MONTH).
- If the ACCUMULATE=TOTAL option is specified, the resulting time series is

O1MAR1999	40
O1APR1999	.
O1MAY1999	90

- If the ACCUMULATE=AVERAGE option is specified, the resulting time series is

O1MAR1999	20
O1APR1999	.
O1MAY1999	30

- If the ACCUMULATE=MINIMUM option is specified, the resulting time series is

O1MAR1999	10
O1APR1999	.
O1MAY1999	20

- If the ACCUMULATE=STDDEV option is specified, the resulting time series is

O1MAR1999	14.14
O1APR1999	.
O1MAY1999	17.32

The preceding examples demonstrate that even when the data observations contain no missing values, the accumulated time series can have missing values.

Missing Value Interpretation

Sometimes missing values should be interpreted as truly unknown values and should be retained as missing values in the data table. The forecasting models used by the CESM procedure can effectively handle missing values; see the section “[Missing Value Modeling Issues](#)” on page 353. However, sometimes missing values are known, such as when missing values are created from accumulation and represent no observed values for the variable. In this case, the value for the period should be interpreted as 0 (no values), and the SETMISSING=0 option should be used to cause PROC CESM to recode missing values as 0. In other cases, missing values should be interpreted as global values, such as minimum or maximum values of the accumulated series. The accumulated and missing-value-recoded time series is used in subsequent analyses in PROC CESM.

Transformations

If the TRANSFORM= option is specified in the FORECAST statement, the time series is transformed prior to model parameter estimation and forecasting. Only strictly positive series can be transformed. An error is generated when the TRANSFORM= option is used with a nonpositive series.

Parameter Estimation

All the parameters (smoothing weights) that are associated with the exponential smoothing model that is used to forecast the time series (as specified by the METHOD= option in the PROC CESM statement) are optimized based on the data, with the default parameter restrictions imposed. If the TRANSFORM= option is specified in the FORECAST statement, the transformed time series data are used to estimate the model parameters.

Missing Value Modeling Issues

The treatment of missing values varies with the forecasting model. Missing values after the start of the series are replaced with one-step-ahead predicted values, and the predicted values are used in the smoothing equations.

The treatment of missing values can also be specified in the SETMISSING= option, which changes the missing values prior to modeling.

NOTE: Even if all the observed data are nonmissing, the ACCUMULATE= option can create missing values in the accumulated series (when the data contain no observations for some of the time periods that are specified in the INTERVAL= option in the ID statement).

Forecasting

After the model parameters are estimated, one-step-ahead forecasts are generated for the full range of the accumulated and optionally transformed time series data, and multistep forecasts are generated from the end of the time series to the future time period that is specified in the LEAD= option in the PROC CESM statement. If there are missing values at the end of the time series, the forecast horizon will be greater than that specified by the LEAD= option.

Inverse Transformations

If the TRANSFORM= option is specified in the FORECAST statement, the forecasts of the transformed time series are inverse-transformed. By default, forecasts of the mean (expected value) are generated. If the MEDIAN option is specified in the PROC CESM statement, median forecasts are generated.

Data Table Output

The CESM procedure can create the OUT=, OUTEST=, OUTFOR=, OUTSTAT=, and OUTSUM= data tables. These data tables contain the variables that are specified in the BY statement and statistics that are related to the variables that are listed in the FORECAST statement. In general, if a forecasting step that is related to an output data table fails, the values of this step are not recorded or are set to missing in the related output data table and appropriate error or warning (or both) messages are recorded in the log.

OUT= Data Table

The OUT= data table contains the variables that are specified in the BY, ID, and FORECAST statements. If the ID statement is specified, the ID variable values are aligned and extended based on the ALIGN= and INTERVAL= options in the ID statement. The values of the variables that are specified in the FORECAST statements are accumulated based on the ACCUMULATE= option in the FORECAST statement, and missing values are interpreted based on the SETMISSING= option in the FORECAST statement.

If any of the forecasting steps fail for a particular variable, the variable is extended by missing values.

OUTEST= Data Table

The OUTEST= data table contains observations that are related to the parameter estimation step. The column names of the table are the BY variables and the following names:

NAME	variable name
MODEL	forecasting model
MODELVAR	model variable
DSVAR	data variable
VARTYPE	variable type
TRANSFORM	transformation
COMPONENT	component
COMPMODEL	component model
PARM	parameter name
FACTOR	factor
LAG	lag
SHIFT	shift
EST	value of parameter estimate
STDERR	standard error of parameter estimate
TVALUE	<i>t</i> values of parameter estimate
PVALUE	<i>p</i> -values of parameter estimate

If the parameter estimation step fails for a particular variable, no observations are output to the OUTEST= data table for that variable.

OUTFOR= Data Table

The OUTFOR= data table contains observations that are related to the forecasting step. The column names of the table are the BY variables and the following names:

NAME	variable name
ID Variable	values of the variable specified in the ID statement
ACTUAL	actual values
PREDICT	predicted values
ERROR	prediction errors
STD	prediction standard errors
UPPER	upper confidence limits
LOWER	lower confidence limits

If the forecasting step fails for a particular variable, no observations are recorded in the OUTFOR= data table for that variable. If the TRANSFORM= option is specified in the FORECAST statement, the values in the preceding variables are the inverse-transform forecasts. If the MEDIAN option is specified in the FORECAST statement, the median forecasts are stored; otherwise, the mean forecasts are stored.

OUTSTAT= Data Set

The OUTSTAT= data table contains observations that are related to the statistics of fit. The column names of the table are the BY variables and the following names:

NAME	variable name
REGION	region in which the statistics are calculated. Statistics that are calculated in the fit region are indicated by FIT. Statistics that are calculated in the forecast region (which happens only if the value of the BACK= option is greater than zero) are indicated by FORECAST.
MODEL	model name
DFE	degrees of freedom error
N	number of observations
NOBS	number of observations used
NMISSA	number of missing actuals
NMISSP	number of missing predicted values
NPARMS	number of parameters
TSS	total sum of squares
SST	corrected total sum of squares
SSE	sum of square error
MSE	mean square error
RMSE	root mean square error
UMSE	unbiased mean square error
URMSE	unbiased root mean square error
MAPE	mean absolute percentage error
MAE	mean absolute error
RSQUARE	R-square
ADJRSQ	adjusted R-square
AADJRSQ	Amemiya's adjusted R-square
RWRSQ	random walk R-square
AIC	Akaike's information criterion
AICC	finite sample corrected AIC
SBC	Schwarz Bayesian information criterion
APC	Amemiya's prediction criterion
MAXERR	maximum error
MINERR	minimum error
MAXPE	maximum percentage error
MINPE	minimum percentage error
ME	mean error

MPE	mean percentage error
MDAPE	median absolute percentage error
GMAPE	geometric mean absolute percentage error
MINPPE	minimum predictive percentage error
MAXPPE	maximum predictive percentage error
MPPE	mean predictive percentage error
MAPPE	symmetric mean absolute predictive percentage error
MDAPPE	median absolute predictive percentage error
GMAPPE	geometric mean absolute predictive percentage error
MINSPE	minimum symmetric percentage error
MAXSPE	maximum symmetric percentage error
MSPE	mean symmetric percentage error
SMAPE	symmetric mean absolute percentage error
MDASPE	median absolute symmetric percentage error
GMASPE	geometric mean absolute symmetric percentage error
MINRE	minimum relative error
MAXRE	maximum relative error
MRE	mean relative error
MRAE	mean relative absolute error
MDRAE	median relative absolute error
GMRAE	geometric mean relative absolute error
MASE	mean absolute scaled error
MINAPES	minimum absolute error percentage of standard deviation
MAXAPES	maximum absolute error percentage of standard deviation
MAPES	mean absolute error percentage of standard deviation
MDAPES	median absolute error percentage of standard deviation
GMAPES	geometric mean absolute error percentage of standard deviation

If the statistics of fit cannot be computed for a particular variable, no observations are recorded in the OUTSTAT= data table for that variable. If the TRANSFORM= option is specified, the values in the preceding variables are computed on the basis of the inverse transform forecasts. If the MEDIAN option is specified, the median forecasts are the basis; otherwise, the mean forecasts are the basis.

OUTSUM= Data Table

The OUTSUM= data table contains the variables that are specified in the BY statement in addition to the variables that are listed in this section. The OUTSUM= data table records the summary statistics for each variable that is specified in a FORECAST statement.

The following variables, which are related to summary statistics, are based on the ACCUMULATE= and SETMISSING= options:

NAME	variable name
NOBS	number of observations
N	number of nonmissing observations
NMISS	number of missing observations
MIN	minimum value
MAX	maximum value
MEAN	mean value
STDDEV	standard deviation
STATUS	forecasting status; nonzero values imply that no forecast was generated for the series
START	the starting date of each series
END	the ending date of each series
STARTOBS	the beginning observation number of each series
ENDOBS	the ending observation number of each series

Printed Output

The CESM procedure always prints a summary of the processing that is performed on the time series data. This is extremely useful for gauging the work that is performed by the CAS server when it executes PROC CESM. Printing of other results is best accomplished by the use of targeted data queries to subset and display the information from the tables that are produced by the CESM procedure. For example, you might want to print the OUTFOR= results only for BY groups that have a particular _STATUS_ value in the OUTSUM= table.

Examples: CESM Procedure

Example 9.1: Forecasting of Time Series Data

This example uses retail sales data to illustrate how you can use the CESM procedure to forecast time series data.

The statements in this example assume that your SAS library is named mylib, but you can substitute any appropriately defined SAS library.

The following DATA step creates a data table from data that were recorded monthly at numerous points of sale. The data table, mylib.sales, contains a variable Date (which represents time) and a variable for each sales item. Each value of the Date variable is recorded in ascending order, and the values of each of the other variables represent a single time series.

```
data mylib.sales;
    format date date9.;
    input date : date9. shoes socks laces dresses
          coats shirts ties belts hats blouses;

    datalines;
01JAN1994 3557 3718 6368.80 575 987 10.8200 15.0000 102.600 12410 15013
01FEB1994 5128 4174 8123.20 565 1000 12.1200 15.1000 99.900 13556 12413
01MAR1994 5222 4482 7807.20 406 1005 11.7800 15.3000 102.000 11063 12752

    ... more lines ...

01DEC1998 5399 4795 6075.30 614 1239 21.2000 1.9000 79.700 23004 22044
01JAN1999 6405 4981 6812.10 607 1196 20.7000 14.9000 99.900 20583 26093
;
```

The following CESM procedure statements forecast each of the monthly time series by using the simple exponential smoothing model:

```
proc cesm data=mylib.sales outfor=mylib.nextyear;
    id date interval=month;
    forecast _numeric_ / lead=12 method=simple;
run;
```

The preceding statements generate forecasts for every numeric variable in the input data table mylib.sales for the next 12 months and store these forecasts in the output data table mylib.nextYear. The summary of time series processing is output in [Output 9.1.1](#).

Output 9.1.1 Summary of Time Series Processing
The CESM Procedure

Processing Summary	
CAS table	SALES
Number of analysis variables	10
Number of rows read	122
Number of groups read	1
Memory for group packages (KB)	33
Time to load groups (seconds)	0.0119960308
Minimum time ID	JAN1994
Maximum time ID	JAN1999
Minimum time periods	61
Maximum time periods	61
Number of nodes run	4
Number of nodes with data	3
Number of nodes with groups	1
Number of threads budgeted	1
Minimum thread group count	0
Maximum thread group count	1
Minimum threads active	1
Maximum threads active	1
Number of groups processed by submitted code	1
Number of groups failing	0
Elapsed time to process groups (seconds)	0.0730199814

The following statements plot the forecasts for the sale of belts, blouses, and laces:

```
%macro plotActualPredict (ds,timeId,var,refValue,
                        xStart,xEnd,xBy,xLabel,yStart,yEnd,yBy,yLabel);
    proc sgplot data=&ds. (where=(_name_="&var."));
        series x=&timeId. y=actual / markers lineattrs=(color=red)
            markerattrs=(symbol=circlefilled color=red);
        series x=&timeId. y=predict / markers lineattrs=(color=blue)
            markerattrs=(symbol=asterisk color=blue);
        reffline &refValue. / axis=x;
        xaxis values=(&xStart. to &xEnd. by &xBy.) label=&xLabel;
        yaxis values=(&yStart. to &yEnd. by &yBy.) label=&yLabel minor;
    run;
%mend;

%plotActualPredict(mylib.nextyear, date, belts, '01JAN1999'd,
    '01JAN1994'd, '01DEC2000'd, year, 'Date',
    20, 140, 20, 'Sales');

%plotActualPredict(mylib.nextyear, date, blouses, '01JAN1999'd,
    '01JAN1994'd, '01DEC2000'd, year, 'Date',
    8000, 36000, 4000, 'Sales');
```

```
%plotActualPredict(mylib.nextyear, date, laces, '01JAN1999'd,
'01JAN1994'd, '01DEC2000'd, year, 'Date',
5000, 10000, 1000, 'Sales');
```

The plots are shown in [Output 9.1.2](#), [Output 9.1.3](#), and [Output 9.1.4](#). The historical actual values and their predicted values are shown to the left of the reference line, and the forecasts for the next 12 monthly periods are shown to the right. For simple exponential smoothing models, the forecasts are constant. The plots seem to indicate that the fit of the predicted values to the actual values is not good.

Output 9.1.2 Retail Sales Forecast Plots (Belts)

Output 9.1.3 Retail Sales Forecast Plots (Blouses)

Output 9.1.4 Retail Sales Forecast Plots (Laces)

The following statements forecast each of the monthly time series by using the default METHOD=BEST option:

```
proc cesm data=mylib.sales outfor=mylib.nextyear outest=mylib.salesEst;
  id date interval=month;
  forecast _numeric_ / lead=12;
run;
```

The best method for each variable is selected according to the criterion (RMSE, the default value, in this case). The following statements plot the forecasts for the sale of belts, blouses, and laces:

```
%plotActualPredict(mylib.nextyear, date, belts, '01JAN1999'd,
  '01JAN1994'd, '01DEC2000'd, year, 'Date',
  20, 140, 20, 'Sales');

%plotActualPredict(mylib.nextyear, date, blouses, '01JAN1999'd,
  '01JAN1994'd, '01DEC2000'd, year, 'Date',
  8000, 36000, 4000, 'Sales');
```

```
%plotActualPredict(mylib.nextyear, date, laces, '01JAN1999'd,
'01JAN1994'd, '01DEC2000'd, year, 'Date',
5000, 10000, 1000, 'Sales');
```

The plots are shown in [Output 9.1.5](#), [Output 9.1.6](#), and [Output 9.1.7](#). The fit of the predicted values to the actual values seems much better, so you might have more confidence in these forecasts.

Output 9.1.5 Retail Sales Forecast Plots (Belts)

Output 9.1.6 Retail Sales Forecast Plots (Blouses)

Output 9.1.7 Retail Sales Forecast Plots (Laces)

The following statements print the methods that are selected for each variable, as shown in [Output 9.1.8](#):

```
data salesEst; set mylib.salesEst; run;
proc sort data=salesEst nodupkey; by _name_ _compmodel_; run;
proc print data=salesEst label noobs;
  var _name_ _compmodel_;
  label _name_='Variable' _compmodel_='Method';
run;
```

Output 9.1.8 Best Method for Each Variable

Variable	Method
belts	SEASONAL
blouses	WINTERS
coats	ADDWINTERS
dressses	SEASONAL
hats	ADDWINTERS
laces	ADDWINTERS
shirts	ADDWINTERS
shoes	ADDWINTERS
socks	ADDWINTERS
ties	SEASONAL

Example 9.2: Forecasting of Transactional Data

This example illustrates how you can use the CESM procedure to forecast transactional data.

The statements in this example assume that your SAS library is named mylib, but you can substitute any appropriately defined SAS library.

The following DATA step creates a data table from data that were recorded at several internet websites. The data table mylib.websites contains a variable Time (which represents time) and the variables Engine, Boats, Cars, and Planes, which represent internet website data. Each value of the Time variable is recorded in ascending order, and the values of each of the other variables represent a transactional data series.

```
data mylib.websites(label="Transactional internet data");

    /*- time variable definition -*/
    keep time;
    format time datetime.;
    label time="Time of Web Hit";
    starttime = '12mar2000:00:00:00'dt; /*- Sunday -*/
    seedtime = 1234321;

    /*- cars variable definition -*/
    keep cars;
    format cars best12.;
    label cars="Number of Car Web Hits";
    seedcar = 1234321;

    /*- boats variable definition -*/
    keep boats;
    format boats best12.;
    label boats="Number of Boat Web Hits";
    seedboat = 1234321;

    /*- planes variable definition -*/
    keep planes;
    format planes best12.;
    label planes="Number of Planes Web Hits";
```

```

seedplane = 1234321;

/*- engines variable definition -*/
keep engines;
format engines best12.;
label engines="Number of Engine Web Hits";
seedengine = 1234321;

/*- simulate the data -*/
do day = 1 to 30;
    season = abs(4 - mod(day,7));
    nhits = ceil(10*ranuni(seedtime));
    intv = 24*3600*ranuni(seedtime)/nhits;
    do hits = 1 to nhits;

        /*- randomly generate the next time -*/
        intv = intv + 24*3600*ranuni(seedtime)/nhits;
        intv = int(intv);
        time = intnx( 'DTDAY', starttime, day );
        time = intnx( 'DTSECOND', time, intv );

        /*- randomly generate car data -*/
        cars = 1000 + 600*day + 1000*season
            + 10*rannor(seedcar);
        cars = int(cars);

        /*- randomly generate boats data -*/
        boats = 1000 + 1000*season +
            + 10*rannor(seedboat);
        boats = int(boats);

        /*- randomly generate planes data -*/
        planes = 1000 - 10*day +
            + 10*rannor(seedplane);
        planes = int(planes);

        /*- randomly generate engines data -*/
        engines = 1000 + 1*cars - 2*boats + 4*planes
            + 10*rannor(seedengine);
        engines = int(engines);

        output;
    end;
end;

run;

```

The following CESM procedure statements forecast each of the transactional data series:

```

proc cesm data=mylib.websites outfor=mylib.nextweek;
    id time interval=dtday accumulate=total;
    forecast boats cars planes / lead=7 method=simple;
run;

```

The preceding statements accumulate the data into a daily time series, generate forecasts for the Boats, Cars,

and Planes variables in the input data table mylib.websites for the next week, and store the forecasts in the mylib.nextWeek data table, which is specified in the OUTFOR= option.

The following statements plot the forecasts that are related to the internet data:

```
%plotActualPredict(mylib.nextweek, time, boats, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 50000, 10000, 'Web Hits');

%plotActualPredict(mylib.nextweek, time, cars, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 250000, 50000, 'Web Hits');

%plotActualPredict(mylib.nextweek, time, planes, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 12000, 2000, 'Web Hits');
```

The plots are shown in [Output 9.2.1](#), [Output 9.2.2](#), and [Output 9.2.3](#). The historical data and their fits are shown to the left of the reference line, and the forecasts for the next seven days are shown to the right.

Output 9.2.1 Internet Data Forecast Plots (Boats)

Output 9.2.2 Internet Data Forecast Plots (Cars)

Output 9.2.3 Internet Data Forecast Plots (Planes)

Example 9.3: Specifying the Forecasting Model

This example illustrates how you can use the CESM procedure to specify different models for different series. Internet data from the previous example are used for this illustration.

The statements in this example assume that your SAS library is named `mylib`, but you can substitute any appropriately defined SAS library.

This example forecasts the Boats variable by using the seasonal exponential smoothing model (SEASONAL), the Cars variable by using the Winters (multiplicative) model (WINTERS), and the Planes variable by using the log Winters (additive) model (ADDWINTERS). The following CESM procedure statements forecast each of the transactional data series based on these requirements:

```
proc cesm data=mylib.websites outfor=mylib.nextweek;
  id time interval=dtday accumulate=total;
  forecast boats / lead=7 method=seasonal;
  forecast cars / lead=7 method=winters;
  forecast planes / lead=7 method=addwinters transform=log;
run;
```

The following statements plot the forecasts that are related to the internet data:

```
%plotActualPredict(mylib.nextweek, time, boats, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 50000, 10000, 'Web Hits');

%plotActualPredict(mylib.nextweek, time, cars, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 250000, 50000, 'Web Hits');

%plotActualPredict(mylib.nextweek, time, planes, '11APR2000:00:00:00'dt,
    '13MAR2000:00:00:00'dt, '18APR2000:00:00:00'dt, dtweek, 'Time of Web Hit',
    0, 12000, 2000, 'Web Hits');
```

The plots are shown in [Output 9.3.1](#), [Output 9.3.2](#), and [Output 9.3.3](#). The historical data and their fits are shown to the left of the reference line, and the forecasts for the next seven days are shown to the right.

Output 9.3.1 Internet Data Forecast Plots (Boats)

Output 9.3.2 Internet Data Forecast Plots (Cars)

Output 9.3.3 Internet Data Forecast Plots (Planes)

Overview: CNTSELECT Procedure

The CNTSELECT (count regression) procedure analyzes regression models in which the dependent variable takes nonnegative integer or count values. The dependent variable is usually an *event count*, which refers to the number of times an event occurs. For example, an event count might represent the number of ship accidents per year for a given fleet. In count regression, the conditional mean $E(y_i | \mathbf{x}_i)$ of the dependent variable y_i is assumed to be a function of a vector of covariates $\mathbf{x}_i$.

The models that PROC CNTSELECT supports can contain main effects that consist of both continuous and classification variables and interaction effects of these variables. The models can also include constructed effects such as splines. The procedure offers effect-selection methods along with capabilities for customizing the model selection process by using various selection and stopping criteria.

The Poisson (log-linear) regression model is the most basic model that explicitly takes into account the nonnegative integer-valued aspect of the outcome. For this model, the probability of an event count is determined by a Poisson distribution, where the conditional mean of the distribution is a function of a vector of covariates. However, the basic Poisson regression model is limited because it forces the conditional mean of the outcome to equal the conditional variance. This assumption is often violated in real-life data. Negative binomial regression is an extension of Poisson regression in which the conditional variance can exceed the conditional mean. Also, a common characteristic of count data is that the number of zeros in the sample exceeds the number of zeros that are predicted by either the Poisson or negative binomial model. Zero-inflated Poisson (ZIP) and zero-inflated negative binomial (ZINB) models explicitly model the production of zero counts to account for excess zeros and also enable the conditional variance of the outcome to differ from the conditional mean.

In zero-inflated models, additional zeros occur with probability φ_i , which is determined by a separate model, $\varphi_i = F(\mathbf{z}_i' \boldsymbol{\gamma})$, where F is the normal or logistic distribution function that results in a probit or logistic model and $\mathbf{z}_i$ is a set of covariates.

PROC CNTSELECT Features

The CNTSELECT procedure estimates the parameters of a count regression model by using maximum likelihood or Bayesian techniques.

The CNTSELECT procedure supports the following models for count data:

- Poisson regression
- Conway-Maxwell-Poisson regression
- negative binomial regression with quadratic and linear variance functions (Cameron and Trivedi 1986)
- zero-inflated Poisson (ZIP) model (Lambert 1992)
- zero-inflated Conway-Maxwell-Poisson (ZICMP) model
- zero-inflated negative binomial (ZINB) model
- fixed-effects and random-effects Poisson models for panel data
- fixed-effects and random-effects negative binomial models for panel data

The following list summarizes some basic features of the CNTSELECT procedure:

- has model-building syntax that uses **CLASS** and effect-based **MODEL** statements familiar from SAS/Econometrics analytic procedures
- performs maximum likelihood estimation
- supports multiple link functions
- uses the **WEIGHT** statement for weighted analysis
- uses the **FREQ** statement for grouped analysis
- uses the **OUTPUT** statement to produce a data table that contains predicted probabilities and other observationwise statistics
- uses the **BAYES** statement to perform Bayesian estimation for all models except Conway-Maxwell-Poisson models and panel models
- uses the **PRIOR** statement to set prior distributions for Bayesian estimation
- supports effect-selection methods

PROC CNTSELECT Compared with Other SAS Procedures

The CNTSELECT procedure provides count-data modeling functionality comparable to that of the HPCOUNTREG and COUNTREG procedures in SAS/ETS software.

PROC CNTSELECT Compared with the HPCOUNTREG Procedure

The functionality of the CNTSELECT procedure closely resembles that of the HPCOUNTREG procedure, which is a high-performance procedure. The CNTSELECT procedure is the next generation of the HPCOUNTREG procedure, and it was developed specifically for SAS Viya. Both procedures are capable of running on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads on multiple machines.

The CNTSELECT procedure provides all the functionality of the HPCOUNTREG procedure and also provides Bayesian estimation techniques.

PROC CNTSELECT Compared with the COUNTREG Procedure

This release of the CNTSELECT procedure contains some, but not all, of the functionality present in the COUNTREG procedure. The COUNTREG procedure provides the following features, which are not present in the CNTSELECT procedure:

- spatial effect models
- scoring by using an item store

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;  
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CNTSELECT Procedure

The CNTSELECT procedure is similar in use to other regression model procedures in the SAS System. For example, the following statements are used to estimate a Poisson regression model:

```
proc cntselect data=mylib.one;
  model y = x / dist=poisson;
run;
```

The response variable `y` is numeric and has nonnegative integer values.

This section illustrates two simple examples that use PROC CNTSELECT. The data are taken from Long (1997). This study examines how factors such as gender (`fem`), marital status (`mar`), number of young children (`kid5`), prestige of the graduate program (`phd`), and number of articles published by a scientist’s mentor (`ment`) affect the number of articles (`art`) published by the scientist.

The first 10 observations are shown in [Figure 10.1](#).

Figure 10.1 Article Count Data

Obs	art	fem	mar	kid5	phd	ment
1	3	0	1	2	1.38000	8.0000
2	1	0	1	1	3.59000	19.0000
3	0	0	1	1	2.12000	10.0000
4	3	0	1	1	1.80000	4.0000
5	1	0	1	1	3.41000	10.0000
6	2	0	1	0	2.10000	2.0000
7	0	0	1	1	2.26000	5.0000
8	6	0	1	1	3.85000	16.0000
9	2	0	0	0	2.26000	2.0000
10	1	0	1	2	4.29000	10.0000

The following SAS statements estimate the Poisson regression model.

```

/*-- Poisson Regression --*/
proc cntselect data=mylib.long97data;
  model art = fem mar kid5 phd ment / dist=poisson method=quanew;
run;

```

The “Model Fit Summary” table that is shown in [Figure 10.2](#) lists several details about the model. By default, the CNTSELECT procedure uses the Newton-Raphson optimization technique. The maximum log-likelihood value is shown, in addition to two information measures—Akaike’s information criterion (AIC) and Schwarz’s Bayesian information criterion (SBC)—which can be used to compare competing Poisson models. Smaller values of these criteria indicate better models.

Figure 10.2 Estimation Summary Table for a Poisson Regression

The CNTSELECT Procedure

Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	LONG97DATA
Model	Poisson
Log Likelihood	-1651.06
Maximum Absolute Gradient	0.001295
Number of Iterations	11
Optimization Method	Quasi-Newton
AIC	3314.113
SBC	3343.026
Covariance Estimation	Hessian

[Figure 10.3](#) shows the parameter estimates of the model and their standard errors. All covariates are significant predictors of the number of articles, except for the prestige of the program (phd), which has a *p*-value of 0.6271.

Figure 10.3 Parameter Estimates of Poisson Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.304617	0.102982	2.96	0.0031
fem	1	-0.224595	0.054614	-4.11	<.0001
mar	1	0.155243	0.061375	2.53	0.0114
kid5	1	-0.184882	0.040127	-4.61	<.0001
phd	1	0.012823	0.026397	0.49	0.6271
ment	1	0.025543	0.002006	12.73	<.0001

To allow for variance greater than the mean, you can fit the negative binomial model instead of the Poisson model by specifying the DIST=NEGBIN option, as shown in the following statements. Whereas the Poisson model requires that the conditional mean and conditional variance be equal, the negative binomial model allows for overdispersion, in which the conditional variance can exceed the conditional mean.

```

/*-- Negative Binomial Regression --*/
proc cntselect data=mylib.long97data;
  model art = fem mar kid5 phd ment / dist=negbin(p=2) method=quanew;
run;

```

Figure 10.4 shows the fit summary and Figure 10.5 shows the parameter estimates.

Figure 10.4 Estimation Summary Table for a Negative Binomial Regression

The CNTSELECT Procedure

Model Fit Summary	
Dependent Variable	art
Number of Observations	915
Data Set	LONG97DATA
Model	NegBin(p=2)
Log Likelihood	-1560.96
Maximum Absolute Gradient	0.070336
Number of Iterations	12
Optimization Method	Quasi-Newton
AIC	3135.917
SBC	3169.649
Covariance Estimation	Hessian

Figure 10.5 Parameter Estimates of Negative Binomial Regression

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	0.256154	0.138560	1.85	0.0645
fem	1	-0.216404	0.072672	-2.98	0.0029
mar	1	0.150485	0.082106	1.83	0.0668
kid5	1	-0.176423	0.053060	-3.32	0.0009
phd	1	0.015266	0.036040	0.42	0.6719
ment	1	0.029083	0.003470	8.38	<.0001
_Alpha	1	0.441618	0.052967	8.34	<.0001

The parameter estimate for _Alpha of 0.4416 is an estimate of the dispersion parameter in the negative binomial distribution. A t test for the hypothesis $H_0 : \alpha = 0$ is provided. It is highly significant, indicating overdispersion ($p < 0.0001$).

The null hypothesis $H_0 : \alpha = 0$ can be also tested against the alternative $\alpha > 0$ by using the likelihood ratio test, as described by Cameron and Trivedi (1998, pp. 45, 77–78). The likelihood ratio test statistic is equal to $-2(\mathcal{L}_P - \mathcal{L}_{NB}) = -2(-1651 + 1561) = 180$, which is highly significant, providing strong evidence of overdispersion.

Syntax: CNTSELECT Procedure

The following statements are available in the CNTSELECT procedure. Items within angle brackets (< >) or square brackets ([]) are optional.

```

PROC CNTSELECT <options> ;
  BAYES <options> ;
  BOUNDS bound1 [ , bound2 ... ] ;
  BY variables ;
  CLASS variable <(options)> ... <variable <(options)> > </ global-options> ;
  DISPLAY <table-list> </ options> ;
  DISPLAYOUT table-spec-list </ options> ;
  DISPMODEL dependent variable ~ <dispersion-related regressors> ;
  EFFECT name=effect-type(variables </ options>) ;
  FREQ freq-variable ;
  INIT initialization1 < , initialization2 ... > ;
  MODEL dependent-variable = regressors </ options> ;
  OUTPUT <output-options> ;
  PRIOR parameter-list ~ distribution ;
  RESTRICT restriction1 [ , restriction2 ... ] ;
  SELECTION < METHOD=method <(method-options)> > <options> ;
  TEST equation1 < , equation2 ... > </ test-options> ;
  VIEWSTORE / options ;
  WEIGHT variable </ option> ;
  ZEROMODEL dependent-variable ~ zero-inflated-regressors </ options> ;

```

There can be only one MODEL statement. Any ZEROMODEL, DISPMODEL, OUTPUT, INIT, BOUNDS, RESTRICT, or TEST statement, if used, must appear after the MODEL statement. There can be no more than one ZEROMODEL statement and no more than one DISPMODEL statement. Multiple INIT, BOUNDS, RESTRICT, and TEST statements are allowed. The BAYES statement is not compatible with the BOUNDS, DISPMODEL, RESTRICT, SELECTION, or TEST statement. If a FREQ or WEIGHT statement is specified more than once, the variable specified in the first instance is used.

Functional Summary

Table 10.1 summarizes the statements and options used with the CNTSELECT procedure.

Table 10.1 Functional Summary

Description	Statement	Option
Data Table Options		
Specifies the input data table	PROC CNTSELECT	DATA=
Specifies the identification variable for panel data analysis	PROC CNTSELECT	GROUPID=
Writes estimates to an output data table	OUTPUT	OUT=
Specifies BY-group processing	BY	

Table 10.1 *continued*

Description	Statement	Option
Specifies the classification variables	CLASS	
Specifies an optional frequency variable	FREQ	
Specifies an optional weight variable	WEIGHT	
Printing Control Options		
Prints the correlation matrix of the estimates	PROC CNTSELECT	CORRB
Prints the covariance matrix of the estimates	PROC CNTSELECT	COVB
Prints the parameter labels without truncating	PROC CNTSELECT	EXTENDPARMLENGTH
Suppresses the normal printed output	PROC CNTSELECT	NOPRINT
Requests all printing options	PROC CNTSELECT	PRINTALL
Prints timing information	PROC CNTSELECT	PRINTTIMING
Prints the names used internally for the parameters	PROC CNTSELECT	PRINTINTERNALNAMES
Options to Control the Optimization Process		
Selects the iterative minimization method to use	PROC CNTSELECT	METHOD=
Specifies maximum number of iterations allowed	PROC CNTSELECT	MAXITER=
Specifies maximum number of function calls	PROC CNTSELECT	MAXFUNC=
Specifies the upper limit of CPU time in seconds	PROC CNTSELECT	MAXTIME=
Sets boundary restrictions on parameters	BOUNDS	
Sets initial values for parameters	INIT	
Sets linear restrictions on parameters	RESTRICT	
Model Estimation Options		
Specifies the dispersion variables	DISPMODEL	
Specifies the type of model	PROC CNTSELECT	DIST=
Specifies the type of covariance matrix	PROC CNTSELECT	COVEST=
Specifies the type of error components model for panel data	MODEL	ERRORCOMP=
Suppresses the intercept parameter	MODEL	NOINT
Specifies the offset variable	MODEL	OFFSET=
Specifies the parameterization for the Conway-Maxwell-Poisson (CMP) model	MODEL	PARAMETER=
Specifies the zero-inflated offset variable	ZEROMODEL	OFFSET=
Specifies the zero-inflated link function	ZEROMODEL	LINK=
Specifies the constructed regression effects	EFFECT	
Regression Effect-Selection Options		
Specifies the selection method	SELECTION	METHOD=
Specifies how to apply the STOP= criterion	SELECTION	STOPHORIZON=
Regression Effect-Selection Method Options		
Specifies a criterion for choosing the best model at each step	SELECTION	CHOOSE=

Table 10.1 *continued*

Description	Statement	Option
Specifies that the competitive form of the stepwise selection method be used	SELECTION	COMPETITIVE
Specifies the maximum number of effects in the model	SELECTION	MAXEFFECTS=
Specifies the maximum number of selection steps	SELECTION	MAXSTEPS=
Specifies the minimum number of effects in the model	SELECTION	MINEFFECTS=
Specifies a criterion to decide which effects enter or leave the model at each step	SELECTION	SELECT=
Specifies a criterion for stopping the selection process	SELECTION	STOP=
Bayesian Markov Chain Monte Carlo (MCMC) Options		
Specifies the number of burn-in iterations	BAYES	NBURNIN=
Specifies the number of Markov chains to run during the sampling phase	BAYES	NCHAIN=
Specifies the number of iterations to run during the sampling phase	BAYES	NSAMPLE=
Specifies the MCMC sampler and its options	BAYES	SAMPLER=
Specifies the random number generator seed	BAYES	SEED=
Controls the thinning of the Markov chain	BAYES	THIN=
Bayesian Output Tables		
Displays MCMC diagnostics	BAYES	DIAGNOSTICS=
Displays MCMC diagnostics for each Markov chain	BAYES	DIAGNOSTICS(BYCHAIN)=
Displays the settings used for all MCMC diagnostics	BAYES	DIAGNOSTICS(SETTINGS)=
Displays a summary of all parameters and their priors	BAYES	PRIORSUMMARY
Displays the settings used for the MCMC sampler	BAYES	SAMPLERSETTINGS
Displays a summary of the MCMC sampler used	BAYES	SAMPLERSUMMARY
Displays posterior summary statistics	BAYES	STATISTICS=
Displays posterior summary statistics for each Markov chain	BAYES	STATISTICS(BYCHAIN)=
Bayesian Posterior Sample		
Specifies options for saving a SAS data table for the posterior sample	BAYES	OUTPOST=
Bayesian Prior Options		
Specifies the Cauchy prior distribution	PRIOR	CAUCHY()
Specifies the gamma prior distribution	PRIOR	GAMMA()
Specifies the inverse gamma prior distribution	PRIOR	IGAMMA()

Table 10.1 *continued*

Description	Statement	Option
Specifies the normal prior distribution	PRIOR	NORMAL()
Specifies the square root gamma prior distribution	PRIOR	SQRTGAMMA()
Specifies the square root inverse gamma prior distribution	PRIOR	SQRTIGAMMA()
Specifies the t prior distribution	PRIOR	T()
Specifies the uniform prior distribution	PRIOR	UNIFORM()
Output Control Options		
Specifies the ODS tables to display	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	
Specifies the output item store to preserve the properties of the model and the results of fitting the model	PROC CNTSELECT	STORE=
Outputs SAS variables to the output data table	OUTPUT	COPYVAR=
Outputs the estimates of dispersion for the CMP model	OUTPUT	DISPERSION
Outputs the estimates of $G\Delta = \mathbf{g}_i' \boldsymbol{\delta}$ for the CMP model	OUTPUT	GDELTA=
Outputs the estimates of λ for the CMP model	OUTPUT	LAMBDA=
Outputs the estimates of ν for the CMP model	OUTPUT	NU=
Outputs the estimates of μ for the CMP model	OUTPUT	MU=
Outputs the estimates of mode for the CMP model	OUTPUT	MODE=
Outputs the probability that the response variable will take the current value	OUTPUT	PROB=
Outputs probabilities for particular response values	OUTPUT	PROBCOUNT()
Outputs expected value of response variable	OUTPUT	PRED=
Outputs the estimates of variance for the CMP model	OUTPUT	VARIANCE=
Outputs estimates of $\mathbf{XBeta} = \mathbf{x}_i' \boldsymbol{\beta}$	OUTPUT	XBETA=
Outputs estimates of $\mathbf{ZGamma} = \mathbf{z}_i' \boldsymbol{\gamma}$	OUTPUT	ZGAMMA=
Outputs probability of a zero value as a result of the zero-generating process	OUTPUT	PROBZERO=

PROC CNTSELECT Statement

PROC CNTSELECT <options> ;

The following *options* can be used in the PROC CNTSELECT statement.

Input Data Table Options

DATA=*libref.data-table*

names the input data table for PROC CNTSELECT to use. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 378.

data-table specifies the name of the input data table.

GROUPID=*variable*

specifies an identification variable when a panel data model is estimated. The identification variable is used as a cross-sectional ID variable.

Item Store Option

STORE=*SAS-item-store*

specifies the item store that preserves the properties of the model and the fit results. No information about the model is preserved unless you specify this option.

Printing Options

You can specify the following options in either the PROC CNTSELECT statement or the MODEL statement:

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

EXTENDPARMLENGTH

prints the parameter labels without truncating.

NOPRINT

suppresses all printed output.

PRINTALL

requests all printing options.

PRINTTIMING

prints a timing report.

PRINTINTERNALNAMES

prints internal names assigned to parameters.

Estimation Control Options

You can specify the following options in either the PROC CNTSELECT statement or the MODEL statement:

COVEST=HESSIAN | OP | QML

specifies the type of covariance matrix for the parameter estimates.

The default is COVEST=HESSIAN. You can specify the following values:

HESSIAN	specifies the covariance from the Hessian matrix.
OP	specifies the covariance from the outer product matrix.
QML	specifies the covariance from the outer product and Hessian matrices.

Optimization Control Options

PROC CNTSELECT uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can specify the following *options* in either the PROC CNTSELECT statement or the MODEL statement.

MAXFUNC=*i***MAXFU=*i***

specifies the maximum number of function calls in the optimization process. The default is 1,000.

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually performed can exceed the number of calls that are specified by this option.

MAXITER=*i***MAXIT=*i***

specifies the maximum number of iterations in the optimization process. The default is 200.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. By default, MAXTIME=200. The time that you specify in this option is checked only once at the end of each iteration. Therefore, the actual run time can be much longer than *r*. The actual run time includes the remaining time that is needed to finish the iteration and the time that is needed to generate the output of the results.

METHOD=*value*

specifies the iterative minimization method to use. The default is METHOD=NEWRAP. You can specify the following *values*:

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
NEWRAP	specifies the Newton-Raphson method (this is the default).
NONE	specifies that no optimization be performed beyond using the ordinary least squares method to compute the parameter estimates.
NRRIDG	specifies the Newton-Raphson Ridge method.
QUANEW	specifies the quasi-Newton method.
TRUREG	specifies the trust region method.

BAYES Statement

BAYES < *options* > ;

The BAYES statement controls the Markov chain Monte Carlo sampling scheme that is used to obtain samples from the posterior distribution of the underlying model and data. The BAYES statement is incompatible with the BOUNDS, DISPMODEL, RESTRICT, SELECTION, and TEST statements and with Conway-Maxwell-Poisson and panel models. You can specify the following *options*:

DIAGNOSTICS < (*diag-options*) >=ALL | NONE | *keyword-list* | (*keyword-list*)

DIAG < (*diag-options*) >=ALL | NONE | *keyword-list* | (*keyword-list*)

specifies which diagnostics to produce. If the value of the NCHAIN= option is greater than 1, then instead of the diagnostic tables being produced for each Markov chain, by default the results of the diagnostics for all the chains are appropriately combined and summarized. For more information, see the section “[Using Multiple Chains](#)” on page 37 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or both of the following *diag-options*:

BYCHAIN

produces diagnostic tables for each Markov chain. If NCHAIN=1, then the BYCHAIN option does nothing.

SETTINGS

produces a table of all MCMC diagnostic settings.

If you specify both the BYCHAIN and SETTINGS options, separate them by using a space or a comma. To produce all diagnostics, specify DIAGNOSTICS=ALL. To produce no diagnostics, specify DIAGNOSTICS=NONE. To produce some but not all diagnostics, or to change certain settings of these diagnostics, specify one or more of the following keywords. If you specify multiple keywords, separate them by using spaces.

AUTOCORR <(LAGS=*numeric-list*)>

AC <(LAGS=*numeric-list*)>

computes the autocorrelations at lags that you specify in the *numeric-list*. For more information, see the section “[Autocorrelations](#)” on page 34 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” Elements in the *numeric-list* must be positive integers, and values can be separated either by spaces or by commas. Repeated values are removed. If you omit the LAGS= option, autocorrelations of lags 1, 5, 10, and 50 are computed.

GEWEKE <(geweke-options)>

GEW <(geweke-options)>

computes the Geweke spectral density diagnostics. For more information, see the section “[Geweke Diagnostics](#)” on page 28 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *geweke-options*:

ALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the Geweke test. By default, ALPHA=0.05.

FRAC1=*value*

F1=*value*

specifies the fraction f_1 for the first window. By default, FRAC1=0.1.

FRAC2=*value*

F2=*value*

specifies the fraction f_2 for the second window. By default, FRAC2=0.5.

HEIDELBERGER <(heidel-options)>

HEIDEL <(heidel-options)>

HB <(heidel-options)>

computes the Heidelberg-Welch diagnostic for each variable. For more information, see the section “[Heidelberg-Welch Diagnostics](#)” on page 30 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or more of the following *heidel-options*:

EPSILON=*value*

EPS=*value*

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed. By default, EPSILON=0.1.

HALFWIDTH_ALPHA=*value*

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the halfwidth test. By default, HALFWIDTH_ALPHA=0.05.

STATIONARY_ALPHA=*value*

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test. By default, STATIONARY_ALPHA=0.05.

RAFTERY <(raftery-options)>

RL <(raftery-options)>

computes the Raftery-Lewis diagnostics. For more information, see the section “[Raftery-Lewis Diagnostics](#)” on page 31 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or more of the following *raftery-options*:

ACCURACY=*value*

ACC=*value*

R=*value*

specifies a small positive number *r* as the margin of error for measuring the accuracy of estimation of the quantile. By default, ACCURACY=0.005.

EPSILON=*value*

EPS=*value*

specifies the tolerance level (ϵ , a small positive number) for the stationary test. By default, EPSILON=0.001.

PROBABILITY=*value*

PROB=*value*

S=*value*

specifies the probability *s* of attaining the accuracy of the estimation of the quantile. By default, PROBABILITY=0.95.

QUANTILE=*value*

QUANT=*value*

Q=*value*

specifies the order (*q*, a value between 0 and 1) of the quantile of interest. By default, QUANTILE=0.025.

SUMMARIES <(MAXLAG=*value*)>

SUMMARY <(MAXLAG=*value*)>

SUM <(MAXLAG=*value*)>

computes a summary of MCMC diagnostics for each parameter in the Markov chain, including effective sample size (ESS), Monte Carlo standard error (MCSE), and related diagnostics. For more information about ESS, see the section “[Effective Sample Size](#)” on page 34 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#)”; for more information about MCSE, see the section “[Standard Error of the Mean Estimate](#)” on page 36 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” MAXLAG=*value* specifies the maximum autocorrelation lag to use for computing ESS, which is used to compute MCSE, where *value* must be a positive integer. By default, MAXLAG=250.

By default, DIAGNOSTICS=SUMMARIES.

DISTRIBUTED**DISTRIBUTE**

keeps the data in the input table distributed on the CAS server when the server runs in massively parallel processing (MPP) mode. If you omit this option, instead the data are copied onto each worker for Bayesian inference, and multiple Markov chains are run in parallel. This option is ignored when the CAS server runs in symmetric multiprocessing (SMP) mode. For more information, see the section “[Distributed Data and MCMC](#)” on page 440.

NBURNIN=*number*

BURNIN=*number*

NBI=*number*

specifies the number of burn-in iterations to perform in each Markov chain before the chains are saved. For more information, see the section “[Burn-In, Thinning, and Markov Chain Samples](#)” on page 27 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, NBURNIN=0.

NCHAIN=*number*

NCHAINS=*number*

CHAINS=*number*

specifies the number of Markov chains to run. By default, NCHAIN=1.

NSAMPLE=*number*

NSAM=*number*

NMC=*number*

specifies the number of iterations after tuning and burn-in to save in each Markov chain. For more information, see the section “[Burn-In, Thinning, and Markov Chain Samples](#)” on page 27 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, NSAMPLE=1000.

OUTPOST<(*outpost-options*)>=*libref.data-table*

names the SAS data table to contain the posterior sample. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 378. You can specify the following *outpost-options*:

DETAILED

saves any relevant additional variables, such as auxiliary variables, in the SAS data table. The random walk Metropolis (RWM) sampler without the [TRANSFORM](#) option has no additional variables to save. With the TRANSFORM option, the SAS data table also includes the transformed version of each parameter and the log posterior of the transformed parameters. When you use the No-U-Turn Sampler (NUTS) by specifying the [SAMPLER=NUTS](#) option, the SAS data table includes those additional variables, as well as the tree height that is achieved at every iteration.

WARMUP

saves warmup (tuning and burn-in) iterations in the SAS data table. This option is not available for the random walk Metropolis (RWM) sampler.

PRIORSUMMARY <(priorsum-option)>

PRIORSUM <(priorsum-option)>

produces a summary of all parameters in the model and their prior distributions. You can specify the following *priorsum-option*:

SHOWNAMES

NAMES

adds a column that displays the names of all parameters in the model. These are the names that you use to specify prior distributions on those parameters.

SAMPLER=NUTS <(nuts-options)> | **RWM** <(rwm-options)>

SAMPLING=NUTS <(nuts-options)> | **RWM** <(rwm-options)>

specifies how to sample from the posterior distribution. By default, SAMPLER=RWM.

NUTS <(nuts-options)>

samples from the posterior distribution by using the No-U-Turn Sampler. You can specify the following *nuts-options*:

DELTA=number

TARGETRATE=number

RATE=number

specifies the target Metropolis acceptance rate δ for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, DELTA=0.8.

MASSTUNE=NONE | **WINDOWED** <(windowed-options)>

specifies the mass matrix tuning method for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, MASSTUNE=WINDOWED. You can specify the following values:

NONE

specifies no mass matrix tuning. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440.

WINDOWED <(windowed-options)>

WINDOW <(windowed-options)>

WIN <(windowed-options)>

specifies the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. You can specify the following *windowed-options*:

EXPANDRATE=number

EXPRATE=number

RATE=number

specifies the window expansion rate γ for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, EXPANDRATE=2.

FINALWINDOW=number

FINAL=number

specifies the size of the final tuning window n_K for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, FINALWINDOW=50.

INITWINDOW=number

INIT=number

specifies the size of the initial tuning window n_1 for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, INITWINDOW=75.

MIDWINDOW=number

MID=number

specifies the size of the first middle tuning window n_2 for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, MIDWINDOW=25.

OVERLAPPING

OVERLAP

OVER

uses overlapping windows for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440.

MAXHEIGHT=number

MAXDEPTH=number

MAXTREE=number

specifies the maximum height of the binary tree $J_{\max}$ for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. To see how many times the algorithm reaches the maximum tree height during sampling, use the [SAMPLERSUMMARY](#) option. By default, MAXHEIGHT=10.

MAXHEIGHTKILL=k | INFINITY

MAXDEPTHKILL=k | INFINITY

MAXTREEKILL=k | INFINITY

specifies the maximum number of times the No-U-Turn Sampler can reach the maximum binary tree height before the simulation stops. To see how many times the algorithm reaches the maximum tree height during sampling, use the [SAMPLERSUMMARY](#) option. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. You can specify the following values:

k

specifies the maximum number of times. If $k=0$, then there is no maximum.

INFINITY**INFTY****INF**

specifies no maximum number of times.

By default, MAXHEIGHTKILL=0.

NTUNE=number**NTU=number**

specifies the number of iterations n_{tune} for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440. By default, NTUNE=2000.

RWM <(rwm-options)>

samples from the posterior distribution by using the random walk Metropolis scheme. You can specify the following *rwm-options*:

ACCTOL=value**ATOL=value**

specifies the tolerance ϵ for the acceptance rate during the tuning process of the random walk Metropolis (RWM) sampler. For more information, see the section “[Scale Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, ACCTOL=0.075.

INITSCALE=value**SCALE=value**

specifies the initial scale parameter(s) c^{cur} of the RWM proposal distribution. For more information, see the section “[Scale Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, INITSCALE=2.38.

NTUNE=number**NTU=number**

specifies the number of iterations n_{tune} for each tuning stage of the random walk Metropolis sampler. For more information, see the section “[Tuning the Random Walk Metropolis Sampler](#)” on page 439. By default, NTUNE=500.

NTUNESTAGE=number

specifies the number of tuning stages n_{stage} . For more information, see the section “[Tuning the Random Walk Metropolis Sampler](#)” on page 439. By default, NTUNESTAGE=24.

TARGETRATE=value**RATE=value****DELTA=value**

specifies the target acceptance rate δ of the random walk Metropolis sampler. For more information, see the section “[Tuning Random Walk Metropolis Algorithms](#)” on page 19 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, TARGETRATE=0.234.

TRANSFORM**TRANS**

transforms all parameters to an unconstrained space and implements the random walk Metropolis sampler on the unconstrained space. For more information, see the section “[Parameter Transformation](#)” on page 25 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

TUNEWEIGHT=*value*

WEIGHT=*value*

WT=*value*

specifies the tuning weight w to use during the tuning phase of the random walk Metropolis sampler to tune the proposal covariance matrix. For more information, see the section “[Covariance Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, TUNEWEIGHT=0.75.

SAMPLERSETTINGS**SAMSETTINGS****SAMSET**

produces a summary of the MCMC sampler settings that are used to sample from the posterior distribution, including tuning settings.

SAMPLERSUMMARY<(VERBOSE)>**SAMSUMMARY**<(VERBOSE)>**SAMSUM**<(VERBOSE)>

produces a summary of the MCMC sampler that is used to sample from the posterior distribution. For the RWM sampler, this option produces a table of the Metropolis acceptance rates. For NUTS, this option produces a table of the Metropolis acceptance rates as well as a table of NUTS diagnostics. You can specify the following suboption:

VERBOSE

produces a more detailed summary of the MCMC sampler. For the RWM sampler, this option does nothing. For NUTS, this option produces a table of the final mass matrix that is used after tuning. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 440.

SEED=*number*

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If you do not specify this option, or if you specify a nonpositive seed, a random seed is generated by reading the time of day from the computer’s clock.

STATISTICS<(stat-option)>=**ALL** | **NONE** | *keyword* | (*keyword-list*)

STATISTIC<(stat-option)>=**ALL** | **NONE** | *keyword* | (*keyword-list*)

STATS<(stat-option)>=**ALL** | **NONE** | *keyword* | (*keyword-list*)

STAT<(stat-option)>=**ALL** | **NONE** | *keyword* | (*keyword-list*)

specifies which posterior summary statistics to produce. If the value of the NCHAIN= option is greater than 1, then instead of the posterior summary statistics being computed separately for each Markov chain, by default the posterior summary statistics are computed by using all chains. For more information, see the section “[Using Multiple Chains](#)” on page 37 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *stat-option*:

BYCHAIN

produces posterior summary statistics tables for each Markov chain. If NCHAIN=1, then the BYCHAIN option does nothing.

To produce all statistics, specify STATISTICS=ALL. To produce no statistics, specify STATISTICS=NONE. To produce some but not all statistics, or to change certain settings of these statistics, specify one or more of the following keywords. If you specify multiple keywords, separate them by using spaces.

CORR**COR**

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

INTERVAL <(interval-option)>**INTERVALS** <(interval-option)>**INT** <(interval-option)>

produces equal-tail posterior credible intervals and highest posterior density (HPD) credible intervals. For more information, see the sections “[Interval Estimation](#)” on page 10 and “[Summary Statistics](#)” on page 35 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *interval-option*:

ALPHA=*numeric-list*

ALPHAS=*numeric-list*

computes posterior credible intervals at the levels that you specify in the *numeric-list*. Elements in the *numeric-list* must be between 0 and 1, and values can be separated either by spaces or by commas. Repeated values are removed. Each value in the *numeric-list* produces a pair of 100(1-*value*)% equal-tail and HPD intervals for each parameter. By default, ALPHA=0.05, which yields the 95% credible intervals for each parameter.

SUMMARIES <(summary-option)>**SUMMARY** <(summary-option)>**SUM** <(summary-option)>

produces the means, standard deviations, and percentiles for the posterior sample. For more information, see the section “[Summary Statistics](#)” on page 35 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *summary-option*:

PERCENTILES=*numeric-list*

PERCENTILE=*numeric-list*

PERCENT=*numeric-list*

PERC=*numeric-list*

PCT=*numeric-list*

computes the percentiles of the posterior sample that you specify in the *numeric-list*. Elements in the *numeric-list* must be between 0 and 100, and values can be separated either by spaces or by commas. Repeated values are removed. By default, PERCENTILES=(2.5 25 50 75 97.5), which yields the 2.5th, 25th, 50th, 75th, and 97.5th percentiles, respectively, for each parameter.

By default, STATISTICS=SUMMARIES.

THIN=*k*

THINNING=*k*

thins the Markov chain by using only one of every *k* iterations. For more information, see the section “Burn-In, Thinning, and Markov Chain Samples” on page 27 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” By default, THIN=1.

BOUNDS Statement

BOUNDS *bound1* [, *bound2* ...] ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. You can specify any number of BOUNDS statements.

Each *bound* is composed of parameter names, constants, and inequality operators as follows:

item operator item [*operator item* [*operator item* ...]]

Each *item* is a constant, a parameter name, or a list of parameter names. Each *operator* is <, >, <=, or >=. Parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as '*', '-', '(', or ')'), then you must use the internal name of the parameter in order to refer to that parameter in the BOUNDS statement. You can specify the PRINTINTERNALNAMES option in the PROC CNTSELECT statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, an extra column is added to the “Parameter Estimates” table, which shows the internal name of each parameter.

For more information about how parameters are named, see the section “Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements” on page 433.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints. However, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. For more information, see the section “RESTRICT Statement” on page 413.

The following BOUNDS statement illustrates the use of parameter lists to specify boundary constraints. It constrains the estimates of the parameter for *z* to be negative, the parameters for *x1* through *x10* to be between 0 and 1, and the parameter for *x1* in the zero-inflation model to be less than 1.

```
bounds z < 0,
       0 < x1-x10 < 1,
       Inf_x1 < 1;
```

The BOUNDS statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

BY Statement

BY *variables* ;

A BY statement can be used with PROC CNTSELECT to obtain separate analyses on observations in groups that are defined by the BY *variables*.

CLASS Statement

CLASS *variable* <(options)>... <*variable* <(options)>> </global-options> ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You can list the response variable for binary models in the CLASS statement, but this is not required. Table 10.2 summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section “CLASS Statement” on page 56 in Chapter 4, “Shared Concepts.”

Table 10.2 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable
SPLIT	Splits levels of CLASS variables into independent effects

DISPLAY Statement

DISPLAY <*table-list*> </options> ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[ODS Table Names](#)” on page 445. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

<i>key=value</i>	specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name.
<i>key</i>	specifies <i>key</i> as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 445. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

DISPMODEL Statement

DISPMODEL *dependent-variable* ~ < *dispersion-related-regressors* > ;

The DISPMODEL statement specifies the *dispersion-related-regressors* that are used to model dispersion. This statement is ignored unless you specify either DIST=CMPOISSON or DIST=ZICMPOISSON in the MODEL statement. The *dependent-variable* in the DISPMODEL statement must be the same as the *dependent-variable* in the MODEL statement. The DISPMODEL statement is not compatible with the BAYES statement.

The *dependent-variable* that appears in the DISPMODEL statement is directly used to model dispersion. Each of the q variables to the right of the tilde ($\sim$) has a parameter to be estimated in the regression. For example, let $\mathbf{g}_i'$ be the i th observation's $1 \times (q + 1)$ vector of values of the q dispersion explanatory variables (q_0 is set to 1 for the intercept term). Then the dispersion is a function of $\mathbf{g}_i' \boldsymbol{\delta}$, where $\boldsymbol{\delta}$ is the $(q + 1) \times 1$ vector of parameters to be estimated, the dispersion model intercept is δ_0 , and the coefficients for the q dispersion covariates are $\delta_1, \dots, \delta_q$. If you specify DISP=CMPOISSON in the MODEL statement but do not include a DISPMODEL statement, then only the intercept term δ_0 is estimated. The “Parameter Estimates” table in the displayed output shows the estimates for the dispersion intercept and dispersion explanatory variables; they are labeled with the prefix “Disp_”. For example, the dispersion intercept is labeled “Disp_Intercept”. If you specify Age (a variable in your data table) as a dispersion explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Disp_Age”. The following statements fit a Conway-Maxwell-Poisson model by using the regressors SEX, ILLNESS, and INCOME and by using AGE as a dispersion-related regressor:

```
proc cntselect data=mylib.docvisit;
  model doctorvisits=sex illness income / dist=cmpoisson;
  dispmode doctorvisits ~ age;
run;
```

EFFECT Statement

EFFECT *name=effect-type (variables < / options>)* ;

The EFFECT statement enables you to construct special collections of columns for design matrices. These collections are referred to as *constructed effects* to distinguish them from the usual model effects that are formed from continuous or classification variables, as discussed in the section “GLM Parameterization of Classification Variables and Effects” on page 94 in Chapter 4, “Shared Concepts.”

You can specify the following *effect-types*:

COLLECTION	specifies a collection effect that defines one or more variables as a single effect that has multiple degrees of freedom. The variables in a collection are considered as a unit for purposes of estimation and inference.
MULTIMEMBER MM	specifies a multimember classification effect whose levels are determined by one or more variables that appear in a CLASS statement.
POLYNOMIAL POLY	specifies a multivariate polynomial effect in the specified numeric variables.
SPLINE	specifies a regression spline effect whose columns are univariate spline expansions of one or more variables. A spline expansion replaces the original variable with an expanded or larger set of new variables.

Table 10.3 summarizes the *options* available in the EFFECT statement.

Table 10.3 EFFECT Statement Options

Option	Description
Collection Effects Options	
DETAILS	Displays the constituents of the collection effect
Multimember Effects Options	
DETAILS	Displays the levels of the multimember effect
NOEFFECT	Specifies that observations whose levels are all missing for the multimember variables should have 0 values in the corresponding design matrix columns
STDIZE	Standardizes the design matrix entries so that each observation has a sum of 1
WEIGHT=	Specifies the weight variable for the contributions of each classification effect
Polynomial Effects Options	
DEGREE=	Specifies the degree of the polynomial
DETAILS	Displays details of the specified polynomial
MDEGREE=	Specifies the maximum degree of any variable in a term of the polynomial
NOSEPARATE	Treats the polynomial as a single effect with multiple degrees of freedom
STANDARDIZE=	Specifies centering and scaling suboptions for the variables that define the polynomial

Table 10.3 *continued*

Option	Description
Spline Effects Options	
BASIS=	Specifies the type of basis (B-spline basis or truncated power function basis) for the spline effect
DATABOUNDARY	Uses the extremes of the data as boundary knots for a B-spline basis
DEGREE=	Specifies the degree of the spline effect
DETAILS	Displays the knots and locations for each spline basis function
KNOTMAX=	Requests equally spaced right-side boundary knots starting at the variables' maximum and ending at the KNOTMAX= value
KNOTMETHOD=	Specifies how to construct the knots for the spline effect
KNOTMIN=	Requests equally spaced left-side boundary knots starting at the KNOTMIN= value and ending at the variables' minimum value
NATURALCUBIC	Specifies a natural cubic spline basis for the spline effect
SEPARATE	Treats the spline basis for each variable as a separate effect when multiple variables are specified
SPLIT	Treats each design matrix column as a separate effect for selection methods

For more information about the syntax of these *effect-types* and how columns of constructed effects are computed, see the section “**EFFECT Statement**” on page 62 in Chapter 4, “**Shared Concepts**.”

FREQ Statement

FREQ *freq-variable* ;

The FREQ statement identifies a variable (*freq-variable*) that contains the frequency of occurrence of each observation. PROC CNTSELECT treats each observation as if it appears n times, where n is the value of *freq-variable* for the observation. If the value for the observation is not an integer, it is truncated to an integer. If the value is less than 1 or missing, the observation is not used in the model fitting. When you omit the FREQ statement, each observation is assigned a frequency of 1. The FREQ statement is not compatible with panel models that you specify by using the ERRORCOMP= option. For information about combining the FREQ statement with the **BAYES** statement, see the section “**Bayesian Analysis with Weighted Likelihoods**” on page 440.

INIT Statement

INIT *initialization1* < , *initialization2* ... > ;

The INIT statement sets initial values for parameters in the optimization.

Each *initialization* is written as a parameter or parameter list, followed by an optional equal sign (=), followed by a number:

parameter <=> *number*

Parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)’), then you must use the internal name of the parameter in order to refer to that parameter in the INIT statement. You can specify the PRINTINTERNALNAMES option in the PROC CNTSELECT statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, an extra column is added to the “Parameter Estimates” table, which shows the internal name of each parameter.

For more information about how parameters are named, see the section “[Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements](#)” on page 433.

MODEL Statement

MODEL *dependent-variable* = *regressors* </ options> ;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model. The dependent count variable should take only nonnegative integer values from the input data table. PROC CNTSELECT rounds any positive noninteger count value to the nearest integer. PROC CNTSELECT discards any observation that has a negative count.

Only one MODEL statement can be specified. You can specify the following *options* in the MODEL statement after a slash (/):

DIST=*value*

specifies a type of model to be analyzed. You can specify the following *values*:

POISSON P	specifies the Poisson regression model.
CMPOISSON C CMP	specifies a Conway-Maxwell-Poisson regression model.
NEGBIN(P=1)	specifies the negative binomial regression model that uses a linear variance function.
NEGBIN(P=2) NEGBIN	specifies the negative binomial regression model that uses a quadratic variance function.
ZIPOISSON ZIP	specifies zero-inflated Poisson regression.
ZICMPOISSON ZICMP	specifies a zero-inflated Conway-Maxwell-Poisson regression. The ZERO-MODEL statement must be specified when this model type is specified.
ZINEGBIN ZINB	specifies zero-inflated negative binomial regression.

You can also specify the DIST option in the CNTSELECT statement. The BAYES statement is not compatible with the CMPOISSON and ZICMPOISSON options.

ERRORCOMP=FIXED | RANDOM

specifies a type of conditional panel model to be analyzed. You can specify the following model types:

- | | |
|---------------|---|
| FIXED | specifies a fixed-effect error component regression model. |
| RANDOM | specifies a random-effect error component regression model. |

The BAYES, FREQ, and WEIGHT statements are not compatible with the ERRORCOMP= option.

NOINT

suppresses the intercept parameter.

OFFSET=offset-variable

specifies a variable in the input data table to be used as an offset variable. The *offset-variable* is used to allow the observational units to vary across observations. For example, when the number of shipping accidents could be measured across different time periods or the number of students who participate in an activity could be reported across different class sizes, the observational units need to be adjusted to a common denominator by using the offset variable. The offset variable appears as a covariate in the model with its parameter restricted to 1. The offset variable cannot be the response variable, the zero-inflation offset variable (if any), or any of the explanatory variables. The “Model Fit Summary” table gives the name of the data table variable that is used as the offset variable; it is labeled “Offset.”

PARAMETER=MU | LAMBDA

specifies the parameterization for the Conway-Maxwell-Poisson model. The following parameterizations are supported:

- | | |
|---------------|--|
| LAMBDA | estimates the original Conway-Maxwell-Poisson model (Shmueli et al. 2005). |
| MU | reparameterizes λ as documented by Guikema and Coffelt (2008), where $\mu = \lambda^{1/\nu}$ and the integral part of μ represents the mode, which can be considered a measure of central tendency (mean). |

By default, PARAMETER=MU.

Printing Options

You can specify the following options in either the PROC CNTSELECT statement or the MODEL statement:

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

NOPRINT

suppresses all printed output.

PRINTALL

requests all printing options.

OUTPUT Statement

OUTPUT < *output-options* > ;

The OUTPUT statement creates a new data table that includes variables created by the *output-options*. These variables include the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability of the response variable taking on the current value. Furthermore, if a zero-inflated model was fit, you can request that the output data table contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$ and the probability that the response is zero as a result of the zero-generating process. For the Conway-Maxwell-Poisson model, the estimates of $\mathbf{g}_i' \boldsymbol{\delta}$, λ , ν , μ , mode, variance, and dispersion are also available. Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations that have missing response values to the input data table, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit.

You can specify only one OUTPUT statement. You can specify the following *output-options*:

OUT=*libref.data-table*

names the output data table for PROC CNTSELECT to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

<i>libref</i>	refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about <i>libref</i> , see the section “Using CAS Sessions and CAS Engine Librefs” on page 378.
---------------	--

<i>data-table</i>	specifies the name of the output data table.
-------------------	--

COPYVAR=*SAS-variable-names*

COPYVARS=*SAS-variable-names*

adds SAS variables to the output data table.

PRED=*name*

MEAN=*name*

names the variable to contain the predicted value of the response variable.

PROB=*name*

names the variable to contain the probability that the response variable will take the actual value, $\Pr(Y = y_i)$.

PROBCOUNT(*value1* < *value2* ... >)

outputs the probability that the response variable will take particular values. Each *value* should be a nonnegative integer. If you specify a noninteger, it is rounded to the nearest integer. The *value* can also be a list of the form X TO Y BY Z. For example, PROBCOUNT(0 1 2 TO 10 BY 2 15) requests predicted probabilities for counts 0, 1, 2, 4, 5, 6, 8, 10, and 15. This option is not available for the fixed-effects and random-effects panel models.

PROBZERO=*name*

names the variable to contain the value of φ_i , which is the probability that the response variable will take the value of 0 as a result of the zero-generating process. This variable is written to the output file only if the model is zero-inflated.

VARIANCE=*name*

assigns a name to the variable that contains the estimate of variance.

XBETA=*name*

names the variable to contain estimates of $\mathbf{x}_i' \boldsymbol{\beta}$.

ZGAMMA=*name*

names the variable to contain estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$.

You can specify the following additional *output-options* if you specify a Conway-Maxwell-Poisson regression in the MODEL statement:

DISPERSION=*name*

assigns a name to the variable that contains the value of dispersion.

GDELTA=*name*

assigns a name to the variable that contains estimates of $\mathbf{g}_i' \boldsymbol{\delta}$.

LAMBDA=*name*

assigns a name to the variable that contains the estimate of λ .

MODE=*name*

assigns a name to the variable that contains the integral part of μ (mode).

MU=*name*

assigns a name to the variable that contains the estimate of μ .

NU=*name*

assigns a name to the variable that contains the estimate of ν .

PRIOR Statement

PRIOR *parameter-list* ~ *distribution* ;

The PRIOR statement specifies the prior distribution of the model parameters for Bayesian analysis. You must specify a single parameter or a list of parameters, a tilde (~), and then a distribution with its parameters. You can specify multiple PRIOR statements, although PRIOR statements for parameters that do not exist in the model are ignored. For information about how parameters are named so that you can refer to them when specifying prior distributions, see the section “[Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements](#)” on page 433. Alternatively, specifying the SHOWNAMES suboption of the PRIORSUMMARY option in the BAYES statement displays the names that are used for all parameters in the prior summary table.

You can specify the following *distributions*. All hyperparameters of the distribution must be specified, except LOWER and UPPER, which determine the support of the distribution and allow for truncated versions of many of them. For more information about these *distributions*, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” For more information about truncated prior distributions, see the section “[Truncated Prior Distributions](#)” on page 442.

CAUCHY(*cauchy-options*)

specifies independently and identically distributed [Cauchy distributions](#) for the *parameter-list*.

You must specify the following *cauchy-options*:

LOCATION= μ

LOC= μ

specifies the location parameter of the Cauchy distribution.

SCALE= γ

specifies the scale parameter of the Cauchy distribution, where $\gamma > 0$.

You can also specify the following *cauchy-options*:

LOWER= L | **NEGATIVEINFINITY**

LB= L | **NEGATIVEINFINITY**

specifies the lower bound of the Cauchy distribution, where $L < U$. You can specify the following values:

L

uses L as the lower bound, such that the prior becomes a truncated Cauchy distribution.

NEGATIVEINFINITY

NEGINF

NEGINF

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the Cauchy distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated Cauchy distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

GAMMA(gamma-options)

specifies independently and identically distributed [gamma distributions](#) for the *parameter-list*. You must specify the following *gamma-options*:

SCALE=b

specifies the scale parameter of the gamma distribution, where $b > 0$.

SHAPE=a

specifies the shape parameter of the gamma distribution, where $a > 0$.

You can also specify the following *gamma-options*:

LOWER=L**LB=L**

specifies the lower bound of the gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated gamma distribution.

By default, LOWER=0.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the gamma distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated gamma distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

IGAMMA(*igamma-options*)

specifies independently and identically distributed **inverse gamma distributions** for the *parameter-list*. You must specify the following *igamma-options*:

SCALE= b

specifies the scale parameter of the inverse gamma distribution, where $b > 0$.

SHAPE= a

specifies the shape parameter of the inverse gamma distribution, where $a > 0$.

You can also specify the following *igamma-options*:

LOWER= L **LB**= L

specifies the lower bound of the inverse gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated inverse gamma distribution.

By default, LOWER=0.

UPPER= U | **INFINITY****UB**= U | **INFINITY**

specifies the upper bound of the inverse gamma distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated inverse gamma distribution.

INFINITY

INFTY

INF

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

NORMAL(*normal-options*)

specifies independently and identically distributed **normal distributions** for the *parameter-list*. You must specify the MEAN= *normal-option* and either the SD= or VAR= *normal-option*:

MEAN= μ

specifies the mean parameter of the normal distribution.

SD= σ

specifies the standard deviation parameter of the normal distribution, where $\sigma > 0$.

VAR= σ^2

specifies the variance parameter of the normal distribution, where $\sigma^2 > 0$.

You can also specify the following *normal-options*:

LOWER=L | NEGATIVEINFINITY**LB=L | NEGATIVEINFINITY**

specifies the lower bound of the normal distribution, where $L < U$. You can specify the following values:

L

uses L as the lower bound, such that the prior becomes a truncated normal distribution.

NEGATIVEINFINITY**NEGINF****NEGINF**

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the normal distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated normal distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

SQRTGAMMA(sqrtgamma-options)

specifies independently and identically distributed [square root gamma distributions](#) for the *parameter-list*. You must specify the following *sqrtgamma-options*:

SCALE=b

specifies the scale parameter of the square root gamma distribution, where $b > 0$.

SHAPE=a

specifies the shape parameter of the square root gamma distribution, where $a > 0$.

You can also specify the following *sqrtgamma-options*:

LOWER=L**LB=L**

specifies the lower bound of the square root gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated square root gamma distribution.

By default, LOWER=0.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the square root gamma distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated square root gamma distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

SQRTIGAMMA(*sqrtigamma-options*)

specifies independently and identically distributed [square root inverse gamma distributions](#) for the *parameter-list*. You must specify the following *sqrtigamma-options*:

SCALE=b

specifies the scale parameter of the square root inverse gamma distribution, where $b > 0$.

SHAPE=a

specifies the shape parameter of the square root inverse gamma distribution, where $a > 0$.

You can also specify the following *sqrtigamma-options*:

LOWER=L**LB=L**

specifies the lower bound of the square root inverse gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated square root inverse gamma distribution.

By default, LOWER=0.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the square root inverse gamma distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated square root inverse gamma distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

T(*t-options*)

specifies independently and identically distributed *t* distributions for the *parameter-list*.

You must specify the following *t-options*:

DF= ν

specifies the degrees-of-freedom parameter of the *t* distribution, where $\nu > 0$.

LOCATION= μ

LOC= μ

specifies the location parameter of the *t* distribution.

SCALE= γ

specifies the scale parameter of the *t* distribution, where $\gamma > 0$.

You can also specify the following *t-options*:

LOWER= L | NEGATIVEINFINITY

LB= L | NEGATIVEINFINITY

specifies the lower bound of the *t* distribution, where $L < U$. You can specify the following values:

L

uses *L* as the lower bound, such that the prior becomes a truncated *t* distribution.

NEGATIVEINFINITY

NEGINTY

NEGINF

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER= U | INFINITY

UB= U | INFINITY

specifies the upper bound of the *t* distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated *t* distribution.

INFINITY

INTY

INF

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

UNIFORM(*uniform-options*)

specifies independently and identically distributed **uniform distributions** for the *parameter-list*. You must specify both the following *uniform-options*:

MAX=*M* | INFINITY

specifies the maximum value of the uniform distribution, where $M < m$. You can specify the following values:

M

uses *M* as the maximum value.

INFINITY

INFTY

INF

uses positive infinity as the maximum value, such that the prior becomes an improper uniform prior.

MIN=*m* | NEGATIVEINFINITY

specifies the minimum value of the uniform distribution, where $m < M$. You can specify the following values:

m

uses *m* as the minimum value.

NEGATIVEINFINITY

NEGINFTY

NEGINF

uses negative infinity as the minimum value, such that the prior becomes an improper uniform prior.

RESTRICT Statement

RESTRICT *restriction1* [, *restriction2* ...] ;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each *restriction* is written either as a single linear equation or as a comma-separated list of two or more linear equations. A restriction equation consists of an *expression*, followed by an equality *operator* (=) or an inequality *operator* (<, >, <=, >=), followed by a second *expression*:

expression operator expression

The *operator* can be =, <, >, <=, or >=.

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified by the names Restrict1, Restrict2, and so on. The test statistics and *p*-values for these restrictions are computed using the Lagrange multiplier test that is described in the section “[Tests on Parameters](#)” on page 438. Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

RESTRICT Statement Expressions

A restriction expression is composed of parameter names, constants, and the operators times (*), plus (+), and minus (−). Each restriction expression must be a linear function of the parameters in the model. In addition, no grouping symbols (such as parentheses) are allowed, and the constant factor in any product can appear only on the left-hand side of the times (*) operator.

In the following example, the assumption is that you have a data table in which *y* is the count variable and *x1*–*x3* are continuous variables. The PROC CNTSELECT program uses a RESTRICT statement to impose a restriction on the estimate for the parameter that is associated with the variable *x2*. Thus, in any solution that the optimizer finds, the solution must satisfy the condition that the parameter that is associated with the variable *x2* is equal to 1.5:

```
proc cntselect data=mylib.exrestrict;
  model y = x1-x3;
  restrict x2=1.5;
run;
```

It is important to keep in mind that the parameters that are associated with the variables, not the variables themselves, are restricted. Thus, in the preceding RESTRICT statement, the variable name “*x2*” refers to the parameter that is associated with the variable *x2*, not to the variable itself.

Parameter names are shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as “*”, “-”, “(”, or “)”), then you must use the internal name of the parameter in order to refer to that parameter in the RESTRICT statement. You can specify the PRINTINTERNALNAMES option in the PROC CNTSELECT statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, an extra column is added to the “Parameter Estimates” table, which shows the internal name of each parameter.

For more information about how parameters are named, see the section “[Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements](#)” on page 433.

Restrictions should be consistent and not redundant. All restriction equations in all RESTRICT statements are applied jointly.

The RESTRICT statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

RESTRICT Statement Examples

Examples of valid RESTRICT statements include the following:

```
restrict x1=0.1;
restrict a+b=1;
restrict a-b=0, b+c=1.5;
restrict 2*f=g+h, intercept+f=0;
```

Examples of invalid RESTRICT statements include the following:

```
restrict x1^2=4;
restrict x1*x3=4;
restrict x1/x3=2;
restrict sin(a)=0;
restrict a*0.5=1;
```

```
restrict 2*(f+h)=1;
```

In the first four examples of invalid RESTRICT statements, the equation is nonlinear. The fifth example is invalid because the constant factor (0.5) cannot appear on the right-hand side of the times (*) operator. The last example is invalid because grouping symbols are not allowed.

The set of restrictions must be consistent. For example, you cannot specify the following because the three restrictions are not consistent:

```
restrict f-g=0,
       f-intercept=0,
       g-intercept=1;
```

The following RESTRICT statement constrains the negative binomial dispersion parameter α to 1, which restricts the conditional variance to be $\mu + \mu^2$:

```
restrict _Alpha = 1;
```

SELECTION Statement

SELECTION <METHOD=*method* <(method-options)> >> options > ;

The SELECTION statement performs model selection by examining whether effects should be added to or removed from the model according to rules that are defined by the selection methods. The statement is fully documented in the section “[SELECTION Statement](#)” on page 78 in Chapter 4, “[Shared Concepts](#).” The CNTSELECT procedure supports only a subset of the *method* values and *method-options* that are listed in that section.

You cannot specify both the SELECTION statement and the BAYES statement.

You can use the following *option* to specify the selection method:

METHOD=BACKWARD | FORWARD | FORWARDSWAP | STEPWISE

specifies the selection method to use. You can specify one of the following methods:

BACKWARD	specifies the backward elimination method.
FORWARD	specifies the forward selection method.
FORWARDSWAP	specifies forward-swap selection, which is an extension of the forward selection method.
STEPWISE	specifies the stepwise regression method.

By default, METHOD=STEPWISE. For more information about each of the selection methods, see the section “[Model Selection Methods](#)” on page 102

PROC CNTSELECT supports a specific set of values for the following *method-options*:

CHOOSE=criterion

chooses from the list of models (at each step of the selection process) the model that yields the best value of the specified criterion. PROC CNTSELECT supports only the following values for *criterion*:

- AIC** specifies Akaike's information criterion.
- SBC** specifies the Schwarz Bayesian information criterion.

By default, the value of the CHOOSE= option is the same as the value that you assign to the SELECT= option. For more information, see the detailed description of the [CHOOSE=](#) option.

SELECT=criterion

specifies the criterion that the procedure uses to determine the order in which effects enter or leave at each step of the selection method. PROC CNTSELECT supports the following values for *criterion*:

- AIC** specifies Akaike's information criterion.
- SBC** specifies the Schwarz Bayesian information criterion.

By default, SELECT=SBC. For more information, see the detailed description of the [SELECT=](#) option.

STOP=criterion

specifies a criterion to use to stop the selection process. PROC CNTSELECT supports only the following values for *criterion*:

- AIC** specifies Akaike's information criterion.
- SBC** specifies the Schwarz Bayesian information criterion.

By default, the value of the STOP= option is the same as the value that you assign to the SELECT= option. For more information, see the detailed description of the [STOP=](#) option.

PROC CNTSELECT supports the following *method-options*, which are described in the section “[SELECTION Statement](#)” on page 78 in Chapter 4, “[Shared Concepts](#)”:

- [COMPETITIVE](#)
- [MAXEFFECTS=](#)
- [MAXSTEPS=](#)
- [MINEFFECTS=](#)

PROC CNTSELECT supports the following statement *options*, which are described in the section “[SELECTION Statement](#)” on page 78 in Chapter 4, “[Shared Concepts](#)”:

- [DETAILS=](#)
- [STOPHORIZON=](#)

TEST Statement

`<label:> TEST <'string'> equation1 <, equation2... > /<test-options> ;`

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters that are specified in the preceding MODEL statement.

Each *test* is written either as a single linear *equation* or as a comma-separated list of two or more linear *equations*. A test *equation* specifies a linear hypothesis to be tested and consists of an *expression*, followed by the equality operator (=), followed by a second expression:

expression = *expression*

The rules governing valid test expressions are the same as those for restriction expressions. For more information see the section “[RESTRICT Statement Expressions](#)” on page 414.

All hypotheses in one TEST statement are tested jointly.

You cannot specify both the TEST statement and the BAYES statement.

You can specify the following *test-options* after a slash (/):

ALL

requests Wald, Lagrange multiplier, and likelihood ratio tests.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

WALD

requests the Wald test.

By default, the Wald test is performed.

You can add a label (which is printed in the output) to a TEST statement in two ways: add an unquoted *label* followed by a colon before the TEST keyword, or add a quoted *string* after the TEST keyword. The unquoted *label* cannot contain any spaces. If you include both an unquoted *label* and a quoted *string*, PROC CNTSELECT uses the unquoted *label*. If you specify neither an unquoted *label* nor a quoted *string*, PROC CNTSELECT automatically labels the tests.

The following illustrates the use of the TEST statement:

```
proc cntselect;
  model y = x1 x2 x3;
  test x1 = 0, 1.5 * x2 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0.75;
run;
```

In the example, two separate tests are performed. The first test investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$1.5\beta_2 + 2\beta_3 = 0$$

The second test is labeled “test_int” and investigates the joint hypothesis that

$$\beta_{\text{Intercept}} = 0$$

and

$$\beta_3 = 0.75$$

VIEWSTORE Statement

VIEWSTORE / *options* ;

The VIEWSTORE statement enables you to print various reports that describe the model fitting information that is preserved in an item store. You must have created the item store by using the STORE= option in the PROC CNTSELECT statement. You can specify the following *options*:

ALL

prints the entire contents of the item store.

BYVARVALUES

prints the values of the BY-group variables that were used to fit the model.

CLASSVARLEVELS

prints the classification variables and levels that were used in the model.

COVARIANCES

prints the covariances matrix.

CORRELATIONS

prints the correlations matrix.

FINALESTIMATES

prints the final parameter estimates.

FITMODELSUMMARY

prints the fit model summary.

INITIALESTIMATES

prints the initial parameter estimates.

INSTORE=SAS-item-store

specifies the item store that you want to view.

MINIMAL

prints only the fit model summary and final parameter estimates.

MODELDEFINITION

prints the statements that defined the model.

NONE

suppresses printing.

OPTIMIZERSETTINGS

prints the optimizer settings that were used to fit the model.

WEIGHT Statement

WEIGHT *variable* </ *option* > ;

The WEIGHT statement specifies a variable to supply weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

The following *option* can be added to the WEIGHT statement after a slash (/):

NONNORMALIZE

does not normalize the weights. (By default, the weights are normalized so that they add up to the actual sample size. The weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size.) If the weights are required to be used as they are, then specify the NONNORMALIZE option.

The WEIGHT statement is not compatible with panel models that you specify by using the ERRORCOMP= option. For information about combining the WEIGHT statement with the BAYES statement, see the section “Bayesian Analysis with Weighted Likelihoods” on page 440.

ZEROMODEL Statement

ZEROMODEL *dependent-variable* ~ *zero-inflated-regressors* < / *options* > ;

The ZEROMODEL statement is required if either ZIP or ZINB is specified in the DIST= option in the MODEL statement. If ZIP or ZINB is specified, then the ZEROMODEL statement must follow the MODEL statement. The dependent variable in the ZEROMODEL statement must be the same as the dependent variable in the MODEL statement.

The zero-inflated (ZI) regressors appear in the equation that determines the probability (φ_i) of a zero count. Each of these q variables has a parameter to be estimated in the regression. For example, let $\mathbf{z}'_i$ be the i th observation's $1 \times (q + 1)$ vector of values of the q ZI explanatory variables (w_0 is set to 1 for the intercept term). Then φ_i is a function of $\mathbf{z}'_i \boldsymbol{\gamma}$, where $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of parameters to be estimated. (The zero-inflated intercept is γ_0 ; the coefficients for the q zero-inflated covariates are $\gamma_1, \dots, \gamma_q$.) If q is equal to 0 (no ZI explanatory variables are provided), then only the intercept term γ_0 is estimated. The “Parameter Estimates” table in the displayed output shows the estimates for the ZI intercept and ZI explanatory variables; they are labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify

Age (a variable in your data table) as a ZI explanatory variable, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”.

You can specify the following *options* in the ZEROMODEL statement after a slash (/):

LINK=LOGISTIC | NORMAL

specifies the distribution function to use to compute probability of zeros. You can specify the following functions:

LOGISTIC specifies logistic distribution.

NORMAL specifies standard normal distribution.

If this option is omitted, then the default ZI link function is logistic.

OFFSET=zero-inflated-offset-variable

specifies a variable in the input data table to be used as a zero-inflated (ZI) offset variable. The ZI offset variable *zero-inflated-offset-variable* is included as a term, with coefficient restricted to 1, in the equation that determines the probability (ϕ_i) of a zero count and represents an adjustment to a common observational unit. The ZI offset variable cannot be the response variable, the offset variable (if any), or any of the explanatory variables. The name of the data table variable that is used as the ZI offset variable is displayed in the “Model Fit Summary” table, where it is labeled as “Inf_offset”.

Details: CNTSELECT Procedure

Missing Values

Any observations in the input data table that have a missing value for one or more of the regressors are ignored by PROC CNTSELECT and not used in the model fit. PROC CNTSELECT rounds any positive noninteger count values to the nearest integer and ignores any observations that have a negative count.

If the input data table contains any observations that have missing response values but nonmissing regressors, PROC CNTSELECT can compute several statistics and store them in an output data table by using the OUTPUT statement. For example, you can request that the output data table contain the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability that the response variable will take the current value. Furthermore, if a zero-inflated model was fit, you can request that the output data table contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$, and the probability that the response is 0 as a result of the zero-generating process. Note that the presence of such observations (that have missing response values) does not affect the model fit.

Poisson Regression

The most widely used model for count data analysis is Poisson regression. Poisson regression assumes that y_i , given the vector of covariates $\mathbf{x}_i$, is independently Poisson distributed with

$$P(Y_i = y_i | \mathbf{x}_i) = \frac{e^{-\mu_i} \mu_i^{y_i}}{y_i!}, \quad y_i = 0, 1, 2, \dots$$

and the mean parameter—that is, the mean number of events per period—is given by

$$\mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

where $\boldsymbol{\beta}$ is a $(k + 1) \times 1$ parameter vector. (The intercept is β_0 ; the coefficients for the k regressors are $\beta_1, \dots, \beta_k$.) Taking the exponential of $\mathbf{x}_i' \boldsymbol{\beta}$ ensures that the mean parameter μ_i is nonnegative. It can be shown that the conditional mean is given by

$$E(y_i | \mathbf{x}_i) = \mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

Note that the conditional variance of the count random variable is equal to the conditional mean in the Poisson regression model:

$$V(y_i | \mathbf{x}_i) = E(y_i | \mathbf{x}_i) = \mu_i$$

The equality of the conditional mean and variance of y_i is known as *equidispersion*.

The standard estimator for the Poisson model is the maximum likelihood estimator (MLE). Because the observations are independent, the log-likelihood function is written as

$$\mathcal{L} = \sum_{i=1}^N (-\mu_i + y_i \ln \mu_i - \ln y_i!) = \sum_{i=1}^N (-e^{\mathbf{x}_i' \boldsymbol{\beta}} + y_i \mathbf{x}_i' \boldsymbol{\beta} - \ln y_i!)$$

For more information about the Poisson regression model, see [SAS/ETS User's Guide](#).

The Poisson model has been criticized for its restrictive property that the conditional variance equals the conditional mean. Real-life data are often characterized by *overdispersion*—that is, the variance exceeds the mean. Allowing for overdispersion can improve model predictions because the Poisson restriction of equal mean and variance results in the underprediction of zeros when overdispersion exists. The most commonly used model that accounts for overdispersion is the negative binomial model. Conway-Maxwell-Poisson regression enables you to model both overdispersion and underdispersion.

Conway-Maxwell-Poisson Regression

The Conway-Maxwell-Poisson (CMP) distribution is a generalization of the Poisson distribution that enables you to model both underdispersed and overdispersed data. It was originally proposed by Conway and Maxwell (1962), but its implementation to model under- and overdispersed count data is attributed to Shmueli et al. (2005).

Recall that y_i , given the vector of covariates $\mathbf{x}_i$, is independently Poisson-distributed as

$$P(Y_i = y_i | \mathbf{x}_i) = \frac{e^{-\lambda_i} \lambda_i^{y_i}}{y_i!}, \quad y_i = 0, 1, 2, \dots$$

The CMP distribution is defined as

$$P(Y_i = y_i | \mathbf{x}_i, \mathbf{g}_i) = \frac{1}{Z(\lambda_i, \nu_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{\nu_i}}, \quad y_i = 0, 1, 2, \dots$$

where the normalization factor is

$$Z(\lambda_i, \nu_i) = \sum_{n=0}^{\infty} \frac{\lambda_i^n}{(n!)^{\nu_i}}$$

and

$$\lambda_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

$$\nu_i = \exp(-\mathbf{g}_i' \boldsymbol{\delta})$$

The vector $\boldsymbol{\beta}$ is a $(k + 1) \times 1$ parameter vector. (The intercept is β_0 , and the coefficients for the k regressors are $\beta_1, \dots, \beta_k$.) The vector $\boldsymbol{\delta}$ is an $(m + 1) \times 1$ parameter vector. (The intercept is represented by δ_0 , and the coefficients for the m regressors are $\delta_1, \dots, \delta_m$.) The covariates are represented by the vectors $\mathbf{x}_i$ and $\mathbf{g}_i$.

One of the restrictive properties of the Poisson model is that the conditional mean and variance must be equal:

$$E(y_i | \mathbf{x}_i) = V(y_i | \mathbf{x}_i) = \lambda_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

The CMP distribution overcomes this restriction by defining an additional parameter, ν , which governs the rate of decay of successive ratios of probabilities such that

$$P(Y_i = y_i - 1) / P(Y_i = y_i) = \frac{(y_i)^{\nu_i}}{\lambda_i}$$

The introduction of the additional parameter, ν , allows for flexibility in modeling the tail behavior of the distribution. If $\nu = 1$, the ratio is equal to the rate of decay of the Poisson distribution. If $\nu < 1$, the rate of decay decreases, enabling you to model processes that have longer tails than the Poisson distribution's (overdispersed data). If $\nu > 1$, the rate of decay increases in a nonlinear fashion, thus shortening the tail of the distribution (underdispersed data).

The CMP distribution has several special cases. If $\lambda < 1$ and $\nu \rightarrow \infty$, the CMP distribution results in the Bernoulli distribution. In this case, the data can take only the values 0 and 1; this represents an extreme

underdispersion. If $\nu = 1$, the Poisson distribution is recovered along with its equidispersion property. When $\nu = 0$ and $\lambda < 1$, the normalization factor is convergent and forms a geometric series,

$$Z(\lambda_i, 0) = \frac{1}{1 - \lambda_i}$$

and the probability density function becomes

$$P(Y = y_i; \lambda_i, \nu_i = 0) = (1 - \lambda_i) \lambda_i^{y_i}$$

The geometric distribution represents a case of severe overdispersion.

Mean, Variance, and Dispersion for the Conway-Maxwell-Poisson Model

The mean and the variance of the Conway-Maxwell-Poisson distribution are defined as

$$E(Y) = \frac{\partial \ln Z}{\partial \ln \lambda}$$

$$V(Y) = \frac{\partial^2 \ln Z}{\partial^2 \ln \lambda}$$

The CMP distribution does not have closed-form expressions for its moments in terms of its parameters λ and ν . However, the moments can be approximated. Shmueli et al. (2005) use asymptotic expressions for Z to derive $E(Y)$ and $V(Y)$ as

$$E(Y) \approx \lambda^{1/\nu} + \frac{1}{2\nu} - \frac{1}{2}$$

$$V(Y) \approx \frac{1}{\nu} \lambda^{1/\nu}$$

Shmueli et al. (2005) noted that these approximations might not be accurate for underdispersed data ($\nu > 1$) or for values of $\lambda^{1/\nu} < 10$.

In the CMP model, the summation of infinite series is evaluated using a logarithmic expansion. The mean and variance are calculated as follows for the Shmueli et al. (2005) model:

$$E(Y) = \frac{1}{Z(\lambda, \nu)} \sum_{j=0}^{\infty} \frac{j \lambda^j}{(j!)^\nu}$$

$$V(Y) = \frac{1}{Z(\lambda, \nu)} \sum_{j=0}^{\infty} \frac{j^2 \lambda^j}{(j!)^\nu} - E(Y)^2$$

The dispersion is defined as

$$D(Y) = \frac{V(Y)}{E(Y)}$$

Log-Likelihood Function for the Conway-Maxwell-Poisson Model

The log-likelihood function for the Conway-Maxwell-Poisson regression model can be written as

$$\begin{aligned}\mathcal{L} &= \sum_{i=1}^N (y_i \ln(\lambda_i) - v_i \ln(y_i!) - \ln[Z(\lambda_i, v_i)]) \\ &= \sum_{i=1}^N (y_i \mathbf{x}_i' \boldsymbol{\beta} - \exp(-\mathbf{g}_i' \boldsymbol{\delta}) \ln(y_i!) - \ln[Z(\lambda_i, v_i)])\end{aligned}$$

The gradients can be written as

$$\begin{aligned}\mathcal{L}_{\boldsymbol{\beta}} &= \sum_{i=1}^N \left(y_i - \frac{Z_{\lambda}(\lambda_i, v_i)}{Z(\lambda_i, v_i)} \lambda_i \right) \mathbf{x}_i \\ \mathcal{L}_{\boldsymbol{\delta}} &= \sum_{i=1}^N \left(\ln(y_i!) + \frac{Z_v(\lambda_i, v_i)}{Z(\lambda_i, v_i)} \right) v_i \mathbf{g}_i\end{aligned}$$

where $Z_{\lambda}(\lambda_i, v_i)$ is the derivative of $Z(\lambda, v)$ with respect to λ evaluated at $\lambda = \lambda_i$ and $v = v_i$, and $Z_v(\lambda_i, v_i)$ is the derivative with respect to v evaluated at $\lambda = \lambda_i$ and $v = v_i$.

Conway-Maxwell-Poisson Regression: Guikema and Coffelt (2008) Reparameterization

Guikema and Coffelt (2008) propose a reparameterization of the Shmueli et al. (2005) Conway-Maxwell-Poisson model to provide a measure of central tendency that can be interpreted in the context of the generalized linear model. By substituting $\lambda = \mu^v$, you can write the Guikema and Coffelt (2008) formulation as

$$P(Y = y_i; \mu_i, v_i) = \frac{1}{S(\mu_i, v_i)} \left(\frac{\mu_i^{y_i}}{y_i!} \right)^{v_i}$$

where the new normalization factor is defined as

$$S(\mu, v) = \sum_{n=0}^{\infty} \left(\frac{\mu^n}{n!} \right)^v$$

and

$$\mu_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

$$v_i = \exp(-\mathbf{g}_i' \boldsymbol{\delta})$$

In terms of their new formulations, the mean and variance of Y are given as

$$E(Y) = \frac{1}{v} \frac{\partial \ln S}{\partial \ln \mu}$$

$$V(Y) = \frac{1}{v^2} \frac{\partial^2 \ln S}{\partial^2 \ln \mu}$$

They can be approximated as

$$E(Y) \approx \mu + \frac{1}{2\nu} - \frac{1}{2}$$

$$V(Y) \approx \frac{\mu}{\nu}$$

When you specify the PRED= option in the OUTPUT statement, the CNTSELECT procedure calculates the predicted value of the response variable by using the approximation for $E(Y)$ if $\mu > 20$; otherwise the exact formula is used. In PROC CNTSELECT, the mean and variance are calculated according to the following formulas for the Guikema and Coffelt (2008) model:

$$E(Y) = \frac{1}{Z(\lambda, \nu)} \sum_{n=0}^{\infty} \frac{n \mu^{\nu n}}{(n!)^{\nu}}$$

$$V(Y) = \frac{1}{Z(\lambda, \nu)} \sum_{n=0}^{\infty} \frac{n^2 \mu^{\nu n}}{(n!)^{\nu}} - E(Y)^2$$

In terms of the new parameter μ , the log-likelihood function is specified as

$$\mathcal{L} = \sum_{i=1}^N (v_i y_i \ln(\mu_i) - v_i \ln(y_i!) - \ln[S(\mu_i, v_i)])$$

and the gradients are calculated as

$$\mathcal{L}_{\beta} = \sum_{i=1}^N \left(v_i y_i - \frac{S_{\mu}(\mu_i, v_i)}{S(\mu_i, v_i)} \mu_i \right) \mathbf{x}_i$$

$$\mathcal{L}_{\delta} = \sum_{i=1}^N \left(\ln(y_i!) + \frac{S_{\nu}(\mu_i, v_i)}{S(\mu_i, v_i)} - y_i \log \mu_i \right) v_i \mathbf{g}_i$$

where $S_{\mu}(\mu_i, v_i)$ is the derivative of $S(\mu, \nu)$ with respect to μ evaluated at $\mu = \mu_i$ and $\nu = v_i$, and $S_{\nu}(\mu_i, v_i)$ is the derivative with respect to ν evaluated at $\mu = \mu_i$ and $\nu = v_i$. By default, PROC CNTSELECT uses the Guikema and Coffelt (2008) specification. You can estimate the Shmueli et al. (2005) model by specifying the PARAMETER=LAMBDA option in the MODEL statement. If you specify DISP=CMPOISSON in the MODEL statement and you omit the DISPMODEL statement, the model is estimated according to the Lord, Guikema, and Geedipally (2008) specification, where ν represents a single parameter that does not depend on any covariates. The Lord, Guikema, and Geedipally (2008) specification makes the model comparable to the negative binomial model because it has only one parameter.

The dispersion is defined as

$$D(Y) = \frac{V(Y)}{E(Y)}$$

Using the Guikema and Coffelt (2008) specification results in the integral part of μ representing the mode, which is a reasonable approximation of the mean. The dispersion can be written as

$$D(Y) = \frac{V(Y)}{E(Y)} \approx \frac{\frac{\mu}{\nu}}{\mu + \frac{1}{2\nu} - \frac{1}{2}} \approx \frac{1}{\nu}$$

When $\nu < 1$, the variance can be shown to be greater than the mean and the dispersion can be shown to be greater than 1. This is a result of overdispersed data. When $\nu = 1$ and the mean and variance are equal, the dispersion is equal to 1 (Poisson model). When $\nu > 1$, the variance is smaller than the mean and the dispersion is less than 1. This is a result of underdispersed data.

All Conway-Maxwell-Poisson models in PROC CNTSELECT are parameterized in terms of dispersion, where

$$-\ln(\nu) = \delta_0 + \sum_{n=1}^q \delta_n g_n$$

Negative values of $\ln(\nu)$ indicate that the data are approximately overdispersed, and positive values of $\ln(\nu)$ indicate that the data are approximately underdispersed.

Negative Binomial Regression

The Poisson regression model can be generalized by introducing an unobserved heterogeneity term for observation i . Thus, the individuals are assumed to differ randomly in a manner that is not fully accounted for by the observed covariates. This is formulated as

$$E(y_i | \mathbf{x}_i, \tau_i) = \mu_i \tau_i = e^{\mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i}$$

where the unobserved heterogeneity term $\tau_i = e^{\epsilon_i}$ is independent of the vector of regressors $\mathbf{x}_i$. Then the distribution of y_i conditional on $\mathbf{x}_i$ and τ_i is Poisson with conditional mean and conditional variance $\mu_i \tau_i$:

$$f(y_i | \mathbf{x}_i, \tau_i) = \frac{\exp(-\mu_i \tau_i) (\mu_i \tau_i)^{y_i}}{y_i!}$$

Let $g(\tau_i)$ be the probability density function of τ_i . Then, the distribution $f(y_i | \mathbf{x}_i)$ (no longer conditional on τ_i) is obtained by integrating $f(y_i | \mathbf{x}_i, \tau_i)$ with respect to τ_i :

$$f(y_i | \mathbf{x}_i) = \int_0^{\infty} f(y_i | \mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i$$

An analytical solution to this integral exists when τ_i is assumed to follow a gamma distribution. This solution is the negative binomial distribution. If the model contains a constant term, then in order to identify the mean of the distribution, it is necessary to assume that $E(e^{\epsilon_i}) = E(\tau_i) = 1$. Thus, it is assumed that τ_i follows a gamma(θ, θ) distribution with $E(\tau_i) = 1$ and $V(\tau_i) = 1/\theta$,

$$g(\tau_i) = \frac{\theta^\theta}{\Gamma(\theta)} \tau_i^{\theta-1} \exp(-\theta \tau_i)$$

where $\Gamma(x) = \int_0^\infty z^{x-1} \exp(-z) dz$ is the gamma function and θ is a positive parameter. Then, the density of y_i given $\mathbf{x}_i$ is derived as

$$\begin{aligned} f(y_i|\mathbf{x}_i) &= \int_0^\infty f(y_i|\mathbf{x}_i, \tau_i) g(\tau_i) d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i}}{y_i! \Gamma(\theta)} \int_0^\infty e^{-(\mu_i + \theta)\tau_i} \tau_i^{\theta + y_i - 1} d\tau_i \\ &= \frac{\theta^\theta \mu_i^{y_i} \Gamma(y_i + \theta)}{y_i! \Gamma(\theta) (\theta + \mu_i)^{\theta + y_i}} \\ &= \frac{\Gamma(y_i + \theta)}{y_i! \Gamma(\theta)} \left(\frac{\theta}{\theta + \mu_i} \right)^\theta \left(\frac{\mu_i}{\theta + \mu_i} \right)^{y_i} \end{aligned}$$

If you make the substitution $\alpha = \frac{1}{\theta}$ ($\alpha > 0$), the negative binomial distribution can then be rewritten as

$$f(y_i|\mathbf{x}_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i = 0, 1, 2, \dots$$

Thus, the negative binomial distribution is derived as a gamma mixture of Poisson random variables. It has the conditional mean

$$E(y_i|\mathbf{x}_i) = \mu_i = e^{\mathbf{x}_i' \boldsymbol{\beta}}$$

and the conditional variance

$$V(y_i|\mathbf{x}_i) = \mu_i \left[1 + \frac{1}{\theta} \mu_i \right] = \mu_i [1 + \alpha \mu_i] > E(y_i|\mathbf{x}_i)$$

The conditional variance of the negative binomial distribution exceeds the conditional mean. Overdispersion results from neglected unobserved heterogeneity. The negative binomial model with variance function $V(y_i|\mathbf{x}_i) = \mu_i + \alpha \mu_i^2$, which is quadratic in the mean, is referred to as the NEGBIN2 model Cameron and Trivedi (1986). To estimate this model, specify DIST=NEGBIN(P=2) in the MODEL statement. The Poisson distribution is a special case of the negative binomial distribution where $\alpha = 0$. A test of the Poisson distribution can be carried out by testing the hypothesis that $\alpha = \frac{1}{\theta_i} = 0$. A Wald test of this hypothesis is provided (it is the reported t statistic for the estimated α in the negative binomial model).

The log-likelihood function of the negative binomial regression model (NEGBIN2) is given by

$$\begin{aligned} \mathcal{L} &= \sum_{i=1}^N \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) - \ln(y_i!) \right. \\ &\quad \left. - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \right\} \end{aligned}$$

where use of the following fact is made if y is an integer:

$$\Gamma(y + a) / \Gamma(a) = \prod_{j=0}^{y-1} (j + a)$$

Cameron and Trivedi (1986) consider a general class of negative binomial models that have mean μ_i and variance function $\mu_i + \alpha\mu_i^p$. The NEGBIN2 model, with $p = 2$, is the standard formulation of the negative binomial model. Models that have other values of p , $-\infty < p < \infty$, have the same density $f(y_i|\mathbf{x}_i)$, except that α^{-1} is replaced everywhere by $\alpha^{-1}\mu_i^{2-p}$. The negative binomial model NEGBIN1, which sets $p = 1$, has the variance function $V(y_i|\mathbf{x}_i) = \mu_i + \alpha\mu_i$, which is linear in the mean. To estimate this model, specify `DIST=NEGBIN(P=1)` in the `MODEL` statement.

The log-likelihood function of the NEGBIN1 regression model is given by

$$\mathcal{L} = \sum_{i=1}^N \left\{ \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) - \ln(y_i!) - (y_i + \alpha^{-1} \exp(\mathbf{x}_i' \boldsymbol{\beta})) \ln(1 + \alpha) + y_i \ln(\alpha) \right\}$$

For more information about the negative binomial regression model, see *SAS/ETS User's Guide*.

Zero-Inflated Count Regression Overview

The main motivation for using zero-inflated count models is that real-life data frequently display overdispersion and excess zeros. Zero-inflated count models provide a way to both model the excess zeros and allow for overdispersion. In particular, there are two possible data generation processes for each observation. The result of a Bernoulli trial is used to determine which of the two processes to use. For observation i , Process 1 is chosen with probability φ_i and Process 2 with probability $1 - \varphi_i$. Process 1 generates only zero counts. Process 2 generates counts from either a Poisson or a negative binomial model. In general,

$$y_i \sim \begin{cases} 0 & \text{with probability } \varphi_i \\ g(y_i) & \text{with probability } 1 - \varphi_i \end{cases}$$

Therefore, the probability of $\{Y_i = y_i\}$ can be described as

$$\begin{aligned} P(y_i = 0|\mathbf{x}_i) &= \varphi_i + (1 - \varphi_i)g(0) \\ P(y_i|\mathbf{x}_i) &= (1 - \varphi_i)g(y_i), \quad y_i > 0 \end{aligned}$$

where $g(y_i)$ follows either the Poisson or the negative binomial distribution.

If the probability φ_i depends on the characteristics of observation i , then φ_i is written as a function of $\mathbf{z}_i' \boldsymbol{\gamma}$, where $\mathbf{z}_i'$ is the $1 \times (q + 1)$ vector of zero-inflated covariates and $\boldsymbol{\gamma}$ is the $(q + 1) \times 1$ vector of zero-inflated coefficients to be estimated. (The zero-inflated intercept is γ_0 ; the coefficients for the q zero-inflated covariates are $\gamma_1, \dots, \gamma_q$.) The function F that relates the product $\mathbf{z}_i' \boldsymbol{\gamma}$ (which is a scalar) to the probability φ_i is called the zero-inflated link function,

$$\varphi_i = F_i = F(\mathbf{z}_i' \boldsymbol{\gamma})$$

In the CNTSELECT procedure, the zero-inflated covariates are indicated in the `ZEROMODEL` statement. Furthermore, the zero-inflated link function F can be specified as either the logistic function,

$$F(\mathbf{z}_i' \boldsymbol{\gamma}) = \Lambda(\mathbf{z}_i' \boldsymbol{\gamma}) = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

or the standard normal cumulative distribution function (also called the probit function),

$$F(\mathbf{z}'_i \boldsymbol{\gamma}) = \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) = \int_0^{\mathbf{z}'_i \boldsymbol{\gamma}} \frac{1}{\sqrt{2\pi}} \exp(-u^2/2) du$$

The zero-inflated link function is indicated by using the LINK= option in the ZEROMODEL statement. The default ZI link function is the logistic function.

Zero-Inflated Poisson Regression

In the zero-inflated Poisson (ZIP) regression model, the data generation process that is referred to earlier as Process 2 is

$$g(y_i) = \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}$$

where $\mu_i = e^{\mathbf{x}'_i \boldsymbol{\beta}}$. Thus the ZIP model is defined as

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) \exp(-\mu_i) \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\exp(-\mu_i) \mu_i^{y_i}}{y_i!}, \quad y_i > 0 \end{aligned}$$

The conditional expectation and conditional variance of y_i are given by

$$\begin{aligned} E(y_i | \mathbf{x}_i, \mathbf{z}_i) &= \mu_i (1 - F_i) \\ V(y_i | \mathbf{x}_i, \mathbf{z}_i) &= E(y_i | \mathbf{x}_i, \mathbf{z}_i) (1 + \mu_i F_i) \end{aligned}$$

Note that the ZIP model (in addition to the ZINB model) exhibits overdispersion because $V(y_i | \mathbf{x}_i, \mathbf{z}_i) > E(y_i | \mathbf{x}_i, \mathbf{z}_i)$.

In general, the log-likelihood function of the ZIP model is

$$\mathcal{L} = \sum_{i=1}^N \ln [P(y_i | \mathbf{x}_i, \mathbf{z}_i)]$$

After a specific link function (either logistic or standard normal) for the probability φ_i is chosen, it is possible to write the exact expressions for the log-likelihood function and the gradient.

ZIP Model with Logistic Link Function

First, consider the ZIP model in which the probability φ_i is expressed by a logistic link function, namely

$$\varphi_i = \frac{\exp(\mathbf{z}'_i \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}'_i \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned}\mathcal{L} = & \sum_{\{i:y_i=0\}} \ln [\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta}))] \\ & + \sum_{\{i:y_i>0\}} \left[y_i \mathbf{x}_i' \boldsymbol{\beta} - \exp(\mathbf{x}_i' \boldsymbol{\beta}) - \sum_{k=2}^{y_i} \ln(k) \right] \\ & - \sum_{i=1}^N \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})]\end{aligned}$$

ZIP Model with Standard Normal Link Function

Next, consider the ZIP model in which the probability φ_i is expressed by a standard normal link function: $\varphi_i = \Phi(\mathbf{z}_i' \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned}\mathcal{L} = & \sum_{\{i:y_i=0\}} \ln \{ \Phi(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \exp(-\exp(\mathbf{x}_i' \boldsymbol{\beta})) \} \\ & + \sum_{\{i:y_i>0\}} \left\{ \ln [(1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma}))] - \exp(\mathbf{x}_i' \boldsymbol{\beta}) + y_i \mathbf{x}_i' \boldsymbol{\beta} - \sum_{k=2}^{y_i} \ln(k) \right\}\end{aligned}$$

For more information about the zero-inflated Poisson regression model, see *SAS/ETS User's Guide*.

Zero-Inflated Conway-Maxwell-Poisson Regression

In the Conway-Maxwell-Poisson regression model, the data generation process is defined as

$$P(Y_i = y_i | \mathbf{x}_i, \mathbf{z}_i) = \frac{1}{Z(\lambda_i, v_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{v_i}}, \quad y_i = 0, 1, 2, \dots$$

where the normalization factor is

$$Z(\lambda_i, v_i) = \sum_{n=0}^{\infty} \frac{\lambda_i^n}{(n!)^{v_i}}$$

and

$$\lambda_i = \exp(\mathbf{x}_i' \boldsymbol{\beta})$$

$$v_i = \exp(-\mathbf{g}_i' \boldsymbol{\delta})$$

The zero-inflated Conway-Maxwell-Poisson model can be written as

$$\begin{aligned}P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) \frac{1}{Z(\lambda_i, v_i)}, \quad y_i = 0 \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{1}{Z(\lambda_i, v_i)} \frac{\lambda_i^{y_i}}{(y_i!)^{v_i}}, \quad y_i > 0\end{aligned}$$

The conditional expectation and conditional variance of y_i are given respectively by

$$E(y_i | \mathbf{x}_i, \mathbf{z}_i) = (1 - F_i) \frac{1}{Z(\lambda, \nu)} \sum_{j=0}^{\infty} \frac{j \lambda^j}{(j!)^\nu}$$

$$V(y_i | \mathbf{x}_i, \mathbf{z}_i) = (1 - F_i) \frac{1}{Z(\lambda, \nu)} \sum_{j=0}^{\infty} \frac{j^2 \lambda^j}{(j!)^\nu} - E(y_i | \mathbf{x}_i, \mathbf{z}_i)^2$$

The general form of the log-likelihood function for the Conway-Maxwell-Poisson zero-inflated model is

$$\mathcal{L} = \sum_{i=1}^N w_i \ln [P(y_i | \mathbf{x}_i, \mathbf{z}_i)]$$

Zero-Inflated Conway-Maxwell-Poisson Model with Logistic Link Function

For this model, the probability φ_i is expressed by using a logistic link function as

$$\varphi_i = \Lambda(\mathbf{z}_i' \boldsymbol{\gamma}) = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} w_i \ln \left\{ \Lambda(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Lambda(\mathbf{z}_i' \boldsymbol{\gamma})] \frac{1}{Z(\lambda_i, \nu_i)} \right\} \\ & + \sum_{\{i: y_i>0\}} w_i \{ \ln [(1 - \Lambda(\mathbf{z}_i' \boldsymbol{\gamma}))] - \ln(Z(\lambda, \nu)) + (y_i \ln(\lambda) - \nu \ln(y_i!)) \} \end{aligned}$$

Zero-Inflated Conway-Maxwell-Poisson Model with Normal Link Function

For this model, the probability φ_i is specified by using the standard normal distribution function (probit function): $\varphi_i = \Phi(\mathbf{z}_i' \boldsymbol{\gamma})$.

The log-likelihood function is written as

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} w_i \ln \left\{ \Phi(\mathbf{z}_i' \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma})] \frac{1}{Z(\lambda_i, \nu_i)} \right\} \\ & + \sum_{\{i: y_i>0\}} w_i \{ \ln [(1 - \Phi(\mathbf{z}_i' \boldsymbol{\gamma}))] - \ln(Z(\lambda, \nu)) + (y_i \ln(\lambda) - \nu \ln(y_i!)) \} \end{aligned}$$

Zero-Inflated Negative Binomial Regression

The zero-inflated negative binomial (ZINB) model in PROC CNTSELECT is based on the negative binomial model that has a quadratic variance function (when DIST=NEGBIN in the MODEL or PROC CNTSELECT statement). The ZINB model is obtained by specifying a negative binomial distribution for the data generation process referred to earlier as Process 2:

$$g(y_i) = \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}$$

Thus the ZINB model is defined to be

$$\begin{aligned} P(y_i = 0 | \mathbf{x}_i, \mathbf{z}_i) &= F_i + (1 - F_i) (1 + \alpha \mu_i)^{-\alpha^{-1}} \\ P(y_i | \mathbf{x}_i, \mathbf{z}_i) &= (1 - F_i) \frac{\Gamma(y_i + \alpha^{-1})}{y_i! \Gamma(\alpha^{-1})} \left(\frac{\alpha^{-1}}{\alpha^{-1} + \mu_i} \right)^{\alpha^{-1}} \\ &\quad \times \left(\frac{\mu_i}{\alpha^{-1} + \mu_i} \right)^{y_i}, \quad y_i > 0 \end{aligned}$$

In this case, the conditional expectation (E) and conditional variance (V) of y_i are

$$E(y_i | \mathbf{x}_i, \mathbf{z}_i) = \mu_i (1 - F_i)$$

$$V(y_i | \mathbf{x}_i, \mathbf{z}_i) = E(y_i | \mathbf{x}_i, \mathbf{z}_i) [1 + \mu_i (F_i + \alpha)]$$

Like the ZIP model, the ZINB model exhibits overdispersion because the conditional variance exceeds the conditional mean.

ZINB Model with Logistic Link Function

In this model, the probability φ_i is given by the logistic function, namely

$$\varphi_i = \frac{\exp(\mathbf{z}_i' \boldsymbol{\gamma})}{1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})}$$

The log-likelihood function is

$$\begin{aligned} \mathcal{L} &= \sum_{\{i: y_i=0\}} \ln \left[\exp(\mathbf{z}_i' \boldsymbol{\gamma}) + (1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta}))^{-\alpha^{-1}} \right] \\ &+ \sum_{\{i: y_i>0\}} \sum_{j=0}^{y_i-1} \ln(j + \alpha^{-1}) \\ &+ \sum_{\{i: y_i>0\}} \{ -\ln(y_i!) - (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}_i' \boldsymbol{\beta})) + y_i \ln(\alpha) + y_i \mathbf{x}_i' \boldsymbol{\beta} \} \\ &- \sum_{i=1}^N \ln [1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma})] \end{aligned}$$

ZINB Model with Standard Normal Link Function

For this model, the probability φ_i is expressed by the standard normal distribution function (probit function): $\varphi_i = \Phi(\mathbf{z}'_i \boldsymbol{\gamma})$. The log-likelihood function is

$$\begin{aligned} \mathcal{L} = & \sum_{\{i: y_i=0\}} \ln \left\{ \Phi(\mathbf{z}'_i \boldsymbol{\gamma}) + [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] (1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta}))^{-\alpha^{-1}} \right\} \\ & + \sum_{\{i: y_i>0\}} \ln [1 - \Phi(\mathbf{z}'_i \boldsymbol{\gamma})] \\ & + \sum_{\{i: y_i>0\}} \sum_{j=0}^{y_i-1} \{ \ln(j + \alpha^{-1}) \} \\ & - \sum_{\{i: y_i>0\}} \ln(y_i!) \\ & - \sum_{\{i: y_i>0\}} (y_i + \alpha^{-1}) \ln(1 + \alpha \exp(\mathbf{x}'_i \boldsymbol{\beta})) \\ & + \sum_{\{i: y_i>0\}} y_i \ln(\alpha) \\ & + \sum_{\{i: y_i>0\}} y_i \mathbf{x}'_i \boldsymbol{\beta} \end{aligned}$$

For more information about the zero-inflated negative binomial regression model, see *SAS/ETS User's Guide*.

Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements

This section describes how you can refer to the parameters in the MODEL, ZEROMODEL, and DISPMODEL statements when you use the RESTRICT, TEST, BOUNDS, INIT, or PRIOR statement. The following examples use the RESTRICT statement, but the same remarks apply to naming parameters when you use the TEST, BOUNDS, INIT, or PRIOR statement. The names of the parameters can be seen in the “Parameter Estimates” table if you specify the option. If a parameter name contains a blank or some other special character (such as “*”, “-”, “(”, or “)”), then you must use the internal name of the parameter in order to refer to that parameter in the RESTRICT, TEST, BOUNDS, INIT, or PRIOR statement. You can specify the PRINTINTERNALNAMES option in the PROC CNTSELECT statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, an extra column is added to the “Parameter Estimates” table, showing the internal name of each parameter. Alternatively, the SHOWNAMES suboption of the PRIORSUMMARY option displays the internal names that are used for all parameters in the prior summary table.

To impose a restriction on a parameter that is related to a regressor in the MODEL statement, you simply use the name of the regressor itself to refer to its associated parameter. Suppose your model is

```
model y = x1 x2 x5;
```

where x1 through x5 are continuous variables. If you want to restrict the parameter associated with the regressor x5 to be greater than 1.7, then you should use the following statement:

```
RESTRICT x5 > 1.7;
```

To impose a restriction on a parameter associated with a regressor in the ZEROMODEL statement, you can form the name of the parameter by prefixing `Inf_` to the name of the regressor. Suppose your MODEL and ZEROMODEL statements are as follows:

```
model y = x1 x2 x5;
zeromodel y ~ x3 x5;
```

If you want to restrict the parameter related to the x5 regressor in the ZEROMODEL statement to be less than 1.0, then you refer to the parameter as `Inf_x5` and provide the following statement:

```
RESTRICT Inf_x5 < 1.0;
```

Even though the regressor x5 appears in both the MODEL and ZEROMODEL statements, the parameter associated with x5 in the MODEL statement is, of course, different from the parameter associated with x5 in the ZEROMODEL statement. Thus, when the name of a regressor is used in a RESTRICT statement without any prefix, it refers to the parameter associated with that regressor in the MODEL statement. Meanwhile, when the name of a regressor is used in a RESTRICT statement with the prefix `Inf_`, it refers to the parameter associated with that regressor in the ZEROMODEL statement. The parameter associated with the intercept in the ZEROMODEL is named `Inf_Intercept`.

In a similar way, you can form the name of a parameter associated with a regressor in the DISPMODEL statement by prefixing `Dsp_` to the name of the regressor. The parameter associated with the intercept in the DISPMODEL is named `Dsp_Intercept`.

Referring to Class-Level Parameters

When your MODEL includes a classification variable, you can impose restrictions on the parameters associated with each of the levels that are related to the classification variable as follows.

Suppose your classification variable is named `C` and it has three levels: 0, 1, 2. Suppose your model is the following:

```
class C;
model y = x1 x2 C;
```

Adding a classification variable as a regressor to your model introduces additional parameters into your model, each of which is associated with one of the levels of the classification variable. You can form the name of the parameter associated with a particular level of your class variable by inserting the underscore character between the name of the classification variable and the value of the level. Thus, to restrict the parameter associated with level 0 of the classification variable `C` to always be greater than 0.7, you refer to the parameter as `C_0` and provide the following statement:

```
RESTRICT C_0 > 0.7;
```

Referring to Parameters Associated with Interactions between Regressors

When a regressor in your model involves an interaction between other regressors, you can impose restrictions on the parameters associated with the interaction.

Suppose you have the following model:

```
model y = x1 x2 x3*x4;
```

You can form the name of the parameter that is associated with the interaction regressor $x3*x4$ by adding underscores between the variable names and the multiplication sign and by replacing the multiplication sign with an underscore. Thus, $x3_x4$ refers to the parameter that is associated with the interaction regressor $x3*x4$.

Referring to interactions between regressors and classification variables is handled in the same way. Suppose you have a classification variable that is named *C* and has three levels: 0, 1, 2. Suppose that your model is the following:

```
class C;
model y = x1 x2 C*x3;
```

The interaction between the continuous variable *x3* and the classification variable *C* introduces three additional parameters, which are named $x3_C_0$, $x3_C_1$, and $x3_C_2$. Note how, although the order of the terms in the interaction is *C* followed by *x3*, the name of the parameter associated with the interaction is formed by placing the name of the continuous variable *x3* first, followed by three underscores, followed by the name of the classification variable *C*, then an underscore, and then the level value. Once again, depending on the parameterization that you specify in your CLASS statement, for each interaction in your model that involves a classification variable, one of the parameters associated with that interaction might be dropped from your model prior to optimization.

The name of a parameter that is associated with a nested interaction is formed in a slightly different way. Suppose you have a classification variable that is named *C* and has three levels: 0, 1, 2. Suppose that your model is the following:

```
class C;
model y = x1 x2 x3(C);
```

The nested interaction between the continuous variable *x3* and the classification variable *C* introduces three additional parameters, which are named $x3_C_0$, $x3_C_1$, and $x3_C_2$. Note how the name in each case is formed from the name of the regressor by first inserting underscores between each variable name and the left and right parentheses, then by replacing the left and right parentheses with underscores.

Referring to Class Level Parameters with Negative Values

When the value of a level is a negative number, you must replace the minus sign with an 'N' when you form the name of the parameter that is associated with that particular level of the classification variable. For example, suppose that your classification variable is named *D* and has four levels: -1, 0, 1, 2. Suppose that your model is the following:

```
class D;
model y = x1 x2 D;
```

To restrict the parameter that is associated with level -1 of the classification variable *D* to always be less than 0.4, you refer to the parameter as D_N1 and provide the following statement:

```
RESTRICT D_N1 < 0.4;
```

Dropping a Class Level Parameter to Avoid Collinearity

Depending on the parameterization you impose on your classification variable, one of the parameters associated with its levels might be dropped from your model prior to optimization in order to avoid collinearity. For example, when the default parameterization GLM is imposed, the parameter that is associated with the last level of your classification variable is dropped prior to optimization. If you attempt to impose a restriction on a dropped parameter by using the RESTRICT statement, PROC CNTSELECT issues an error message in the log.

For example, suppose again that your classification variable is named C and that it has three levels: 0, 1, 2. Suppose your model is the following:

```
class C;
model y = x1 x2 C;
```

Because no additional options are specified in the CLASS statement, GLM parameterization is assumed. This means that the parameter named C_2 (which is the parameter associated with the last level of your classification variable) will be dropped from your model before the optimizer is invoked. Therefore, an error will be issued if you attempt to restrict the C_2 parameter in any way by referring to it in a RESTRICT statement. For example, the following RESTRICT statement will generate an error:

```
RESTRICT C_2 < 0.3;
```

Referring to Implicit Parameters

Unless you specified the NOINT option, you can impose a restriction on the parameter associated with the Intercept in your model simply by referring to it by name: Intercept.

For certain model types, one or more implicit parameters will be added to your model prior to optimization. You can impose restrictions on these implicit parameters.

For the Poisson model for which ERRORCOMP=RANDOM is specified, PROC CNTSELECT automatically adds the _Alpha parameter to your model.

If no ERRORCOMP= option is specified, for zero-inflated binomial and negative binomial models, PROC CNTSELECT adds the _Alpha parameter to the model. If ERRORCOMP=RANDOM is specified for the zero-inflated binomial and negative binomial models, then PROC CNTSELECT adds two implicit parameters to the model: _Alpha and _Beta.

For Conway-Maxwell Poisson models that do not include a DISPMODEL statement, the _lnNu parameter is added to the model.

Whenever your model type dictates the addition of one or more of these implicit parameters, you can impose restrictions on the implicit parameters by referring to them by name in a RESTRICT statement. For example, if your model type implies the existence of the _Alpha parameter, you can restrict _Alpha to be greater than 0.2 as follows:

```
RESTRICT _Alpha > 0.2;
```

Computational Resources

The time and memory that PROC CNTSELECT requires are proportional to the number of parameters in the model and the number of observations in the data table being analyzed. Less time and memory are required for smaller models and fewer observations. When PROC CNTSELECT is run in the high-performance distributed environment, the amount of time required is also affected by the number of nodes and the number of threads per node as specified in the PERFORMANCE statement.

The method that is chosen to calculate the variance-covariance matrix and the optimization method also affect the time and memory resources. All optimization methods available through the METHOD= option have similar memory use requirements. The processing time might differ for each method, depending on the number of iterations and functional calls needed. The data table is read into memory to save processing time. If not enough memory is available to hold the data, the CNTSELECT procedure stores the data in a utility file on disk and rereads the data as needed from this file, substantially increasing the execution time of the procedure. The gradient and the variance-covariance matrix must be held in memory. If the model has p parameters including the intercept, then at least $8 * (p + p * (p + 1)/2)$ bytes of memory are needed. The processing time is also a function of the number of iterations needed to converge to a solution for the model parameters. The number of iterations that are needed cannot be known in advance. You can use the MAXITER= option to limit the number of iterations that PROC CNTSELECT executes. You can alter the convergence criteria by using the nonlinear optimization options available in the PROC CNTSELECT statement. For a list of all the nonlinear optimization options, see “[Optimization Control Options](#)” on page 387.

Covariance Matrix Types

The COVEST= option in the PROC CNTSELECT statement enables you to specify the estimation method for the covariance matrix. COVEST=HESSIAN estimates the covariance matrix that is based on the inverse of the Hessian matrix; COVEST=OP uses the outer product of gradients; and COVEST=QML produces the covariance matrix that is based on both the Hessian and outer product matrices. Although all three methods produce asymptotically equivalent results, they differ in computational intensity and produce results that might differ in finite samples. The COVEST=OP option provides the covariance matrix that is typically the easiest to compute. In some cases, the OP approximation is considered more efficient than the Hessian or QML approximation because it contains fewer random elements. The QML approximation is computationally the most complex because it requires both the outer product of gradients and the Hessian matrix. In most cases, the OP or Hessian approximation is preferred to QML. The need for QML approximation arises in cases where the model is misspecified and the information matrix equality does not hold. The default is COVEST=HESSIAN.

Tests on Parameters

In general, you can write the tested hypothesis as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is an $r \times 1$ vector-valued function of the parameters θ that is given by the r expressions that you specify in the TEST statement.

Let $\hat{V}$ be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ , and let $\tilde{\theta}$ be the constrained estimate of θ such that $\mathbf{h}(\tilde{\theta}) = 0$. Let

$$A(\theta) = \partial \mathbf{h}(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Using this notation, you compute the test statistics for the three types of tests as follows:

- The Wald test statistic is defined as

$$W = \mathbf{h}'(\hat{\theta}) \left(A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} \mathbf{h}(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

- The Lagrange multiplier test statistic is

$$LM = \lambda' A(\tilde{\theta}) \tilde{V} A'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

- The likelihood ratio test statistic is

$$LR = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For each type of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values that are reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation of its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, because it does not require computation of the constrained estimate $\tilde{\theta}$.

The following statements use the TEST statement to perform a likelihood ratio test:

```
proc cntselect;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

For more information, see *SAS/ETS User's Guide*.

Bayesian Analysis

To perform Bayesian analysis, you must specify a BAYES statement. Unless otherwise stated, all options in this section are options in the BAYES statement.

Bayes' theorem states that the posterior density $\pi(\theta|y)$ can be obtained via

$$\pi(\theta|y) \propto \pi(\theta)L(y|\theta)$$

where θ is a parameter or a vector of parameters and $\pi(\theta)$ is the product of the prior densities that you specify in the **PRIOR** statement. The term $L(y|\theta)$ is the likelihood associated with the model that is implied by the **MODEL** statement. For an introduction to Bayesian analysis, see the section “[Overview](#)” on page 5 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

To perform Bayesian analysis, you must draw a random sample from the posterior density $\pi(\theta|y)$ by using the Markov chain Monte Carlo (MCMC) method. For an introduction to MCMC, see the section “[Markov Chain Monte Carlo Method](#)” on page 16 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, PROC CNTSELECT uses the random walk Metropolis (RWM) algorithm to obtain the posterior sample. For an overview of Metropolis algorithms, see the section “[Metropolis and Metropolis-Hastings Algorithms](#)” on page 17 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” The RWM algorithm requires a proposal distribution to be tuned to match certain features of the posterior distribution. For more information about this tuning process, see the section “[Tuning Random Walk Metropolis Algorithms](#)” on page 19 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

Alternatively, PROC CNTSELECT can use the No-U-Turn Sampler (NUTS) algorithm, a variant of the Hamiltonian Monte Carlo (HMC) algorithm, to obtain the posterior sample. For an overview of HMC and NUTS, see the sections “[Hamiltonian Monte Carlo Sampler](#)” on page 21 and “[No-U-Turn Sampler](#)” on page 22 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” NUTS requires an integrator step size parameter and a mass matrix parameter to be tuned to match certain features of the posterior distribution. For more information about this tuning process, see the section “[Tuning for NUTS](#)” on page 23 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

Additional details specific to PROC CNTSELECT follow.

Tuning the Random Walk Metropolis Sampler

PROC CNTSELECT tunes the random walk Metropolis proposal distribution during a tuning phase that consists of n_{stage} tuning stages, each n_{tune} iterations long. For more information, see the section “[Tuning Random Walk Metropolis Algorithms](#)” on page 19 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” The random walk Metropolis proposal covariance matrix that is defined in that section, COV^{cur} , should approximate the posterior covariance matrix and must be initialized prior to tuning. PROC CNTSELECT always initializes it to the covariance matrix of the maximum likelihood estimates of the model parameters.

Tuning the No-U-Turn Sampler

PROC CNTSELECT tunes both the integrator step size and the mass matrix in a tuning phase that consists of n_{tune} iterations, divided into a sequence of tuning windows. For more information, see the section “[Tuning for NUTS](#)” on page 23 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” The step size is tuned throughout the entire tuning phase in order to achieve a desired Metropolis acceptance rate. The mass matrix is diagonal, and the ideal mass matrix is the diagonal matrix of inverse posterior variances. These posterior variances are learned in the tuning phase. PROC CNTSELECT always initializes the mass matrix to the diagonal matrix of the inverse square standard errors of the maximum likelihood parameter estimates.

Initial Values of the Markov Chain

PROC CNTSELECT starts each Markov chain at the maximum likelihood estimates (MLEs) of the parameters. If the MLE for a particular parameter is outside the support of its prior distribution, then PROC CNTSELECT instead initializes that parameter near the boundary of its prior support.

Bayesian Analysis with Weighted Likelihoods

In PROC CNTSELECT, you can account for sample weights in Bayesian analysis by using the **WEIGHT** statement, provided that the weights are handled properly. The weighted log-likelihood functions in PROC CNTSELECT have the form

$$\ell(\theta) = \sum_{i=1}^n w_i \ell_i(\theta)$$

where $\ell_i(\theta)$ is the log likelihood for observation i , w_i is the corresponding sample weight, and n is the sample size. When $w_i = 1$ for all i , this is equivalent to a nonweighted log likelihood. In this case the weights sum to the sample size.

In the general weighted case, the sum of the weights should still equal the sample size—that is, $\sum_{i=1}^n w_i = n$ —and w_i/n should represent the proportion of the sample size that corresponds to observation i . This ensures that the prior density and likelihood function are weighted correctly in the posterior density. For more information, see Savitsky and Toth (2016).

PROC CNTSELECT normalizes the weights to sum to the sample size by default, so weighted Bayesian analyses are valid. The **NONNORMALIZE** option in the **WEIGHT** statement tells PROC CNTSELECT not to normalize the weights, so it can result in misleading weighted Bayesian analyses and is generally not recommended.

The **FREQ** statement is similar to the **WEIGHT** statement, except that each frequency represents the sample size associated with the corresponding observation. By definition, the sum of the frequencies is equal to the sample size. So you can combine the **BAYES** statement with the **FREQ** statement without issue.

Distributed Data and MCMC

When you use a CAS server that is running in massively parallel processing (MPP) mode, the data are distributed across the workers of the server. Iterative methods such as MCMC can be significantly slower in this context because of communication costs. Additionally, when you request multiple Markov chains by using the **NCHAIN=** option, those chains are independent of each other and can be run in parallel instead of serially. When you perform Bayesian analysis by using the **BAYES** statement on a server in MPP mode, PROC CNTSELECT automatically tries to take advantage of the distributed environment to make MCMC

run as fast as possible. To do this, it automatically copies the data onto each worker machine and divides the number of requested Markov chains among the workers as evenly as possible. Then those workers run their chains in parallel and send their results back to the controller. MCMC is therefore always as slow as the slowest worker—typically one of the workers that have the most Markov chains if the chains cannot be evenly divided among the workers. The fastest possible CAS server configuration has at least as many workers as the number of Markov chains that you request, though there is no benefit to having more workers than chains.

Although copying the data to each of the workers and letting them run their own Markov chains in parallel is fast, it requires the data set to be small enough to fit on each worker machine. You can use the [DISTRIBUTED](#) option to instead keep the data distributed at the cost of a much slower analysis. The [DISTRIBUTED](#) option also enables you to obtain results that are numerically identical to those of PROC CNTSELECT in release 2022.11 and previous releases, which do not automatically copy the data set onto the workers for Bayesian analysis. If the CAS server is running in symmetric multiprocessing (SMP) mode, then the server has only a single machine and the [DISTRIBUTED](#) option does nothing.

Prior Distributions

The PRIOR statement is used to specify the prior distribution of the model parameters. You must specify a list of parameters, a tilde (~), and then a distribution with its parameters. You can specify multiple [PRIOR](#) statements to define independent prior distributions. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable. For information about how parameters are named so that you can refer to them when specifying prior distributions, see the section “[Parameter Naming Conventions for the RESTRICT, TEST, BOUNDS, INIT, and PRIOR Statements](#)” on page 433. Alternatively, the SHOWNAMES suboption of the [PRIORSUMMARY](#) option displays the names that are used in all parameters in the prior summary table.

If a parameter is not associated with a PRIOR statement, then the default choices shown in [Table 10.4](#) are used.

Table 10.4 Default Values for Prior Distributions

Parameter Type	Default Prior Name	Default Prior Specification
Regression, location	Normal	NORMAL(MEAN=0, VAR=1E6)
Scale	Gamma	GAMMA(SHAPE=2, SCALE=100)

For more information about each prior density, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” For information about truncated densities, see the section “[Truncated Prior Distributions](#)” on page 442. For information about why the default prior on the standard deviation parameter is a truncated normal distribution, see the section “[Prior Distributions for Scale Parameters](#)” on page 442.

Prior Distributions for Scale Parameters

A common choice for a prior distribution on variance parameters and other scale parameters is the inverse gamma distribution. This prior can often be problematic in practice, and as a consequence it can even cause computational problems. This is partially because the density puts essentially no probability mass near zero. For more information, see Gelman (2006). The main advantage of the inverse gamma prior is that it is the conditionally conjugate prior for a variance parameter in a normal model; this makes certain sampling algorithms easier to use. For more information, see the section “[Conjugate Priors](#)” on page 9 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” However, the posterior sampler in PROC CNTSELECT does not take advantage of this conjugacy, so there is no computational benefit to using the inverse gamma prior.

Instead, PROC CNTSELECT uses the gamma for the default prior on scale parameters. This density allows for the scale parameter to be estimated arbitrarily close to zero and otherwise removes the problems associated with the inverse gamma prior. In general, if you want to specify prior information on a scale parameter, it is recommended that you encode that information into a gamma distribution, truncated normal distribution, or truncated t distribution.

Truncated Prior Distributions

All prior distributions except the uniform distribution can be turned into truncated prior distributions by using the LOWER and UPPER parameters. By default, LOWER is set to the maximum of the parameter’s lower bound and the specified prior distribution’s lower bound, and UPPER is set to the minimum of the parameter’s upper bound and the specified prior distribution’s upper bound. For example, for `_Alpha`, the dispersion parameter in a negative binomial model, the following statement specifies a truncated normal prior on `_Alpha` with LOWER=0 and UPPER=INFINITY:

```
prior _Alpha ~ normal(mean = 0, var = 1);
```

The density of any truncated prior can be computed from the corresponding untruncated density given in the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#),” as follows. Suppose $\pi(\theta)$ is the prior density for the parameter θ . Then let $\Pi(\theta)$ denote the corresponding CDF, defined by the integral

$$\Pi(\theta) = \int_{-\infty}^{\theta} \pi(x) dx$$

where $\pi(x)$ is taken to be 0 outside its range (for each prior density’s range, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#)”). Then the truncated density is constructed from the untruncated density by using the formula

$$\pi_{L,U}(\theta) = \frac{\pi(\theta)}{\Pi(U) - \Pi(L)}$$

where $L < U$ are the lower and upper truncation bounds, respectively. If the lower truncation bound is the lower bound of π ’s range, then $\Pi(L) = 0$, and similarly if the upper truncation bound is the upper bound of π ’s range, then $\Pi(U) = 1$.

Displayed Output

PROC CNTSELECT produces the following displayed output.

Model Fit Summary

The “Model Fit Summary” table contains the following information:

- dependent (count) variable name
- number of observations used
- number of missing values in data table, if any
- data table name
- type of model that was fit
- error components model type for panel data
- group id variable for panel data
- number of cross sections for panel data
- parameterization for the Conway-Maxwell-Poisson model
- frequency variable name, if any
- weight variable name, if any
- offset variable name, if any
- zero-inflated link function, if any
- zero-inflated offset variable name, if any
- log-likelihood value at solution
- maximum absolute gradient at solution
- number of iterations
- optimization technique used
- AIC value at solution (smaller value indicates better fit)
- SBC value at solution (smaller value indicates better fit)
- covariance matrix estimation method used

A line below the “Model Fit Summary” table indicates whether the algorithm successfully converged.

Parameter Estimates

The “Parameter Estimates” table gives the estimates of the model parameters. In zero-inflated (ZI) models, estimates are also given for the ZI intercept and ZI regressor parameters, which are labeled with the prefix “Inf_”. For example, the ZI intercept is labeled “Inf_intercept”. If you specify “Age” as a ZI regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Inf_Age”. If you do not list any ZI regressors, then only the ZI intercept term is estimated.

If the DISPMODEL statement is specified for the Conway-Maxwell-Poisson model, the estimates are given for the dispersion intercept, and parameters are labeled with the prefix “Dsp_”. For example, the dispersion model intercept is labeled “Dsp_Intercept”. If you specify “Education” as a dispersion model regressor, then the “Parameter Estimates” table labels the corresponding parameter estimate “Dsp_Education”. If you do not list any dispersion regressors, then only the dispersion intercept is estimated.

“_Alpha” is the negative binomial dispersion parameter. The t statistic that is given for “_Alpha” is a test of overdispersion.

Covariance of Parameter Estimates

If you specify the COVB option in the PROC CNTSELECT or MODEL statement, the CNTSELECT procedure displays the estimated covariance matrix, which is defined as the inverse of the information matrix at the final iteration.

Correlation of Parameter Estimates

If you specify the CORRB option in the PROC CNTSELECT or MODEL statement, the CNTSELECT procedure displays the estimated correlation matrix, which is based on the Hessian matrix used at the final iteration.

OUTPUT OUT= Data Table

The OUTPUT statement creates a new data table that contains various estimates that you specify. You can request that the output data table contain the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the probability that the response variable will take the current value. In a zero-inflated model, you can also request that the output data table contain the estimates of $\mathbf{z}_i' \boldsymbol{\gamma}$, and the probability that the response is zero as a result of the zero-generating process. In a Conway-Maxwell-Poisson model, you can also request that the output data table contains estimates of $\mathbf{g}_i' \boldsymbol{\delta}$, λ , ν , μ , mode, variance and dispersion.

Except for the probability of the current value, these statistics can be computed for all observations in which the regressors are not missing, even if the response is missing. By adding observations with missing response values to the input data table, you can compute these statistics for new observations or for settings of the regressors that are not present in the data without affecting the model fit. Because of potential space limitations, the data table that is created by the OUTPUT statement does not contain the variables in the input data table.

ODS Table Names

PROC CNTSELECT assigns a name to each table that it creates. You can use these names to denote the table when you use the Output Delivery System (ODS) to select tables and create output data tables. These table names are listed in [Table 10.5](#).

Table 10.5 ODS Tables Produced by PROC CNTSELECT

Table Name	Description	Statement	Option
BSplineDetails	Basis details for B-spline effects	EFFECT	SPLINE with DETAILS
ClassInfo	Level information from the CLASS statement	CLASS	Default

Examples: The CNTSELECT Procedure

Example 10.1: Zero-Inflated Poisson Model with CLASS Statement

This example shows how to use the CNTSELECT procedure to estimate a zero-inflated Poisson model with a classification variable `Group` that has two levels. The following DATA step generates 10,000 replicates from the zero-inflated Poisson (ZIP) model. The first 5,000 replicates belong to the first group, and the second 5,000 replicates belong to the second group. The model contains seven variables and three variables that correspond to the zero-inflated process.

```
data simulate;
  call streaminit(12345);
  array vars x1-x7;
  array zero_vars z1-z3;

  array parms{7} (.3 .4 .2 .4 -.3 -.5 -.3);
  array zero_parms{3} (-.6 .3 .2);

  intercept=0.5;
  group=1;
  z_intercept=-1;
  theta=0.5;

  do i=1 to 10000;
    sum_xb=0;
    sum_gz=0;
```

```

if i>5000 then do;
    intercept=2;
    group=2;
end;
do j=1 to 7;
    vars[j]=rand('NORMAL',0,1);
    sum_xb=sum_xb+parms[j]*vars[j];
end;
mu=exp(intercept+sum_xb);
y_p=rand('POISSON', mu);

do j=1 to 3;
    zero_vars[j]=rand('NORMAL',0,1);
    sum_gz = sum_gz+zero_parms[j]*zero_vars[j];
end;
z_gamma = z_intercept+sum_gz;
pzero = cdf('LOGISTIC',z_gamma);
cut=rand('UNIFORM');
if cut<pzero then y_p=0;
output;
end;
keep y_p group x1-x7 z1-z3;
run;

```

You can load the data set simulate into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```

data mylib.simulate;
    set simulate;
run;

```

The following statements estimate a zero-inflated Poisson model with the classification variable Group:

```

proc cntselect data=mylib.simulate dist=zip;
    class group;
    model y_p=group x1-x7;
    zeromodel y_p ~ z1-z3;
run;

```

Output 10.1.1 shows the results for the zero-inflated Poisson model.

Output 10.1.1 Zero-Inflated Poisson Model with CLASS Statement

The “Class Level Information” table shows that the classification variable Group has two levels. The “Model Fit Summary” table shows detailed information about the model and indicates that all 10,000 observations were used to fit the model. All parameter estimates in the “Parameter Estimates” table are highly significant and correspond to their theoretical values set during the data generating process.

Example 10.2: Zero-Inflated Poisson Model with BAYES and PRIOR Statements

This example shows how to use the CNTSELECT procedure to estimate a zero-inflated Poisson model by using Bayesian methods, with user-specified priors. The following DATA step generates 1,000 replicates from the zero-inflated Poisson (ZIP) model. The model contains seven variables and three variables that correspond to the zero-inflated process.

```
data bayes_ex;
  call streaminit(12345);
  array vars x1-x7;
  array zero_vars z1-z3;
  array parms{7} (.3 .4 .2 .4 -.3 -.5 -.3);
  array zero_parms{3} (-.6 .3 .2);
  intercept=0.5;
  group=1;
  z_intercept=-1;
  theta=0.5;
  do i=1 to 1000;
    sum_xb=0;
    sum_gz=0;
    if i>500 then do;
      intercept=2;
      group=2;
    end;
    do j=1 to 7;
      vars[j]=rand('NORMAL', 0, 1);
      sum_xb=sum_xb+parms[j]*vars[j];
    end;
    mu=exp(intercept+sum_xb);
    y_p=rand('POISSON', mu);
    do j=1 to 3;
      zero_vars[j]=rand('NORMAL', 0, 1);
      sum_gz = sum_gz+zero_parms[j]*zero_vars[j];
    end;
    z_gamma = z_intercept+sum_gz;
    pzero = cdf('LOGISTIC', z_gamma);
    cut=rand('UNIFORM');
    if cut<pzero then y_p=0;
    output;
  end;
  keep y_p group x1-x7 z1-z3;
run;
```

You can load the data set bayes_ex into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.bayes_ex;
  set bayes_ex;
run;
```

The following statements estimate a zero-inflated Poisson model via Bayesian analysis. Note that the BAYES statement controls the settings for the MCMC sampler and determines which Bayesian output to produce. The PRIOR statements set the prior distributions for the parameters.

```
proc cntselect data=mylib.bayes_ex dist=zip;
  class group;
  model y_p=group x1-x7;
  zeromodel y_p ~ z1-z3;
  bayes seed = 81239 nmc = 10000 sampler = rwm(ntu = 50) priorsummary(shownames);
  prior x1-x7 ~ normal(mean = 0, sd = 10);
  prior group_1 ~ normal(mean = 0, sd = 10, upper = 0);
  prior Intercept ~ normal(mean = 0, sd = 10);
  prior Inf_z1-Inf_z3 ~ normal(mean = 0, sd = 1);
  prior Inf_Intercept ~ normal(mean = 0, sd = 10);
run;
```

Output 10.2.1 shows the results for the zero-inflated Poisson model. The “Prior Summary” table shows detailed information about prior distributions for the parameters in the model. The “Posterior Summaries” table contains two point estimates of the parameters from the posterior samples: the posterior mean and the posterior median (50th percentile). The “MCMC Diagnostic Summaries” table contains basic convergence diagnostics to check whether the Markov chain has converged and whether the sample size is sufficient.

Output 10.2.1 Bayesian Estimation of Zero-Inflated Poisson Model

Example 10.3: Bayesian Analysis Using NUTS with Multiple Chains

This example shows how to use the CNTSELECT procedure to estimate a model in the Bayesian framework by using the No-U-Turn Sampler (NUTS) with multiple Markov chains.

The following DATA step creates the data set DocVisit, which contains information for approximately 5,000 Australian individuals about the number and possible determinants of doctor visits that were made during a two-week interval. This data set contains a subset of variables that are taken from the data set Racd3 that was used by Cameron and Trivedi (1998).

```
data docvisit;
  input sex age agesq income levyplus freepoor
        freerepa illness actdays hscore chcond1 chcond2
        doctorco nondocco hospadmi hospad medicine prescrib nonpresc;
  datalines;
1 0.19 0.0361 0.55 1 0 0 1 4 1 0 0 1 0 0 0 1 1 0
1 0.19 0.0361 0.45 1 0 0 1 2 1 0 0 1 0 0 0 2 1 1
0 0.19 0.0361 0.9 0 0 0 3 0 0 0 0 1 0 1 4 2 1 1
0 0.19 0.0361 0.15 0 0 0 1 0 0 0 0 1 0 0 0 0 0 0
0 0.19 0.0361 0.45 0 0 0 2 5 1 1 0 1 0 0 0 3 1 2
1 0.19 0.0361 0.35 0 0 0 5 1 9 1 0 1 0 0 0 1 1 0
1 0.19 0.0361 0.55 0 0 0 4 0 2 0 0 1 0 0 0 0 0 0

0 0.19 0.0361 0.15 1 0 0 1 0 0 0 0 1 0 0 0 1 1 0
0 0.19 0.0361 0.45 0 0 0 1 0 0 0 0 1 0 0 0 1 1 0

... more lines ...
```

The variable Doctorco represents doctor visits. Additional variables in the data set that you want to evaluate as determinants of doctor visits include Sex (coded as 0=male, 1=female), Age (age in years divided by 100), Illness (number of illnesses during the two-week interval, with five or more coded as five), Income (annual income in Australian dollars divided by 1,000), and Hscore (a score on a general health questionnaire, in which a high score indicates bad health).

You can load the data set DocVisit into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.docvisit;
  set docvisit;
run;
```

The following statements estimate a Poisson regression model in the Bayesian framework by using the No-U-Turn Sampler (NUTS) with multiple Markov chains. NUTS is specified in the **SAMPLER=** option in the BAYES statement, and you can set several values that control the sampler as arguments to the **SAMPLER=NUTS** option. The **NCHAIN=** option controls the number of Markov chains, and the **NSAMPLE=** option controls the size of the posterior sample per chain. PROC CNTSELECT automatically aggregates the results of each chain to create the posterior statistics and MCMC diagnostics tables that you request. The BYCHAIN suboption of the **STATISTICS=** and **DIAGNOSTICS=** options additionally produces those tables separately for each chain. This example produces the “Posterior Summaries” table, the “MCMC Diagnostic Summaries” table, and the “Heidelberger-Welch Diagnostics” table for each chain as well as for all chains

combined.

```
proc cntselect data = mylib.docvisit;
  class sex illness;
  model doctorco=sex illness income hscore;
  bayes seed = 5317 nsample = 2000 nchain = 4
    sampler = nuts(ntune = 2000)
    statistics(bychain) = summary
    diagnostics(bychain) = (summary heidel);
run;
```

Output 10.3.1 shows the Bayesian estimation results. The “Posterior Summaries” table displays the estimates of the posterior mean and posterior quantiles that are computed using all four chains. The other posterior summary statistics tables that the **STATISTICS=** option produces would similarly be computed using all four chains. The “MCMC Diagnostic Summaries” table displays basic convergence diagnostics that are aggregated across all four chains. The “Autocorrelation Diagnostics” table would also be aggregated for multiple chains. For more information about how this aggregation is performed, see the section “Using Multiple Chains” on page 37 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” The “Heidelberger-Welch Diagnostics” table displays a summary of all the Heidelberger-Welch tests that are performed for each chain. Specifically, for each parameter it shows the number of chains that passed each test, as well as the largest number of iterations that were discarded for the stationarity test. The “Geweke Diagnostics” table and the “Raftery-Lewis Diagnostics” table would both be summarized similarly.

Output 10.3.1 Posterior Summaries and MCMC Diagnostics

Detailed results for each chain are available in [Output 10.3.2](#) as a result of the BYCHAIN options. The “Posterior Summaries by Chain” table displays the estimates of the posterior mean and posterior quantiles that are computed separately for each chain. Similarly, the “MCMC Diagnostic Summaries by Chain” table displays basic convergence diagnostics that are computed for each chain, and the “Heidelberger-Welch Diagnostics by Chain” table displays the Heidelberger-Welch diagnostics that are computed for each chain. For more information about the differences between the tables in [Output 10.3.1](#) and [Output 10.3.2](#), see the section “Using Multiple Chains” on page 37 in Chapter 2, “Introduction to Bayesian Analysis Procedures.”

Overview: CPANEL Procedure

The CPANEL procedure analyzes a class of linear econometric models that arise when time series and cross-sectional data are combined. This type of data is called *panel data*. Typical examples of panel data include observations over time on people, households, countries, or firms. For example, in the case of survey data on household income, the panel is created by repeatedly surveying the same households over many years. The individual entities that are followed over time are called *cross sections*.

Regression models for panel data are characterized by an error structure that can be divided into a cross-sectional component, a time component, and an observation-level component. Panel data models can be categorized by the exact structure of the error term and how it interacts with the regression equation. The CPANEL procedure supports the following models:

- one-way and two-way models
- fixed-effects, random-effects, and hybrid models
- instrumental variables (IV) models
- dynamic panel models

A one-way model depends only on the cross section to which the observation belongs. A two-way model depends on both the cross section and the time period to which the observation belongs. The models are called fixed-effects models if the effects are nonrandom and are called random-effects models otherwise.

If the effects are fixed, the models are essentially regression models with dummy variables that correspond to the effects. For fixed-effects models, ordinary least squares (OLS) estimation, with some facility for absorbing the dummy variables, is the best linear unbiased estimator. Random-effects models use a two-stage approach. In the first stage, variance components are estimated by your choice of the methods described by Swamy and Arora (1972); Fuller and Battese (1974); Wansbeek and Kapteyn (1989); Wallace and Hussain (1969); Nerlove (1971). In the second stage, variance components are used to standardize the data, and then OLS regression is performed.

Random-effects models are more efficient than fixed-effects models, and they can estimate effects for variables that do not vary within cross sections. The cost of these added features is that random-effects models carry much more stringent assumptions than their fixed-effects counterparts. The CPANEL procedure also supports models that blend the desirable features of random and fixed effects. These hybrid models are described by Hausman and Taylor (1981) and Amemiya and MaCurdy (1986).

Instrumental variables (IV) models are models that introduce auxiliary regression variables to deal with endogenous regressors—regressors that are correlated with the residual errors. The CPANEL procedure supports IV generalizations of the pooled regression model, the between-groups regression model, the one-way fixed-effects model, the one-way random-effects model, the two-way fixed-effects model, and the two-way random-effects model. For the one-way random-effects model, PROC CPANEL uses methods that were developed by Baltagi (1981). PROC CPANEL can also estimate these models by using the efficient generalized method of moments (GMM).

Dynamic panel models are autoregression models that include lagged versions of the dependent variable as regressors. Examples of such models can be found in Arellano and Bond (1991) and Blundell and Bond (1998). The CPANEL procedure fits these models by using the generalized method of moments (GMM). You can perform GMM on either the difference equations or the full system of difference and level equations.

PROC CPANEL Features

The CPANEL procedure fits panel-data regression models by using various techniques, and does the following:

- provides an **ID** statement for specifying the cross section and time variables
- provides flexible model-building syntax that supports continuous regressors, classification (**CLASS**) variables, interactions, and nested effects
- fits one-way and two-way fixed-effects models
- fits one-way and two-way random-effects models
- fits Hausman and Taylor (1981) models
- fits Amemiya and MaCurdy (1986) models
- fits instrumental variables (IV) regression models
- fits dynamic panel models
- enables you to fit multiple models by using multiple estimators, all within one procedure call

- provides a **COMPARE** statement for producing customizable comparisons of various models and estimators
- provides a **TEST** statement for performing linear tests of hypotheses
- provides a **RESTRICT** statement for imposing linear parameter constraints
- provides an **OUTPUT** statement for producing a data table that contains predictions and residuals

Because the CPANEL procedure runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode on CAS
- exploits all the available cores and concurrent threads. For information about how PROC CPANEL uses threads, see the section “[Multithreading](#)” on page 108 in Chapter 4, “[Shared Concepts](#).”

PROC CPANEL Compared with Other SAS Procedures

The CPANEL procedure models panel data in a way that is comparable to how the HPPANEL and PANEL procedures in SAS/ETS software do this.

PROC CPANEL Compared with the HPPANEL Procedure

The functionality of the CPANEL procedure closely resembles that of the HPPANEL procedure, which is a high-performance procedure. The CPANEL procedure is the next generation of the HPPANEL procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads.

The CPANEL procedure provides all the functionality of the HPPANEL procedure, and also provides the following:

- instrumental variable (IV) regression estimators
- dynamic panel estimators, as described by Arellano and Bond (1991) and Blundell and Bond (1998)
- Hausman and Taylor (1981) and Amemiya and MaCurdy (1986) estimators, which are hybrids of fixed-effects and random-effects estimators
- estimation of the fixed-effects model by first differencing (FD)
- Swamy and Arora (1972) estimates of variance components
- tables that compare parameters from multiple models and multiple estimation methods
- the option to specify a character variable as the cross section ID variable
- the option to not specify a time series ID variable when time is not relevant to the estimation

PROC CPANEL Compared with the PANEL Procedure

The CPANEL procedure provides the following functionality not found in PROC PANEL:

- instrumental variables (IV) regression estimators
- Swamy and Arora (1972) estimates of variance components
- support for estimation when the data contain cross sections that consist of only one observation
- the option to specify a character variable as the cross section ID variable
- the option to not specify a time-series ID variable when time is not relevant to the estimation

The PANEL procedure parameterizes the fixed-effects model by using the last ordered cross section and the latest time point as reference categories. The CPANEL procedure uses a mean-centered parameterization.

The PANEL procedure supports the Da Silva (1975) method for serial correlation, and the Parks (1967) method for first-order autocorrelation. These two methods are not provided in this release of the CPANEL procedure.

The PANEL procedure offers a wide variety of postfitting analyses, such as model specification tests and tests for unit root. The PANEL procedure is also able to construct utility data sets that contain lagged variables and data reformatted from wide form to long form. This release of the CPANEL procedure is limited in postfitting and data-generating functionality, because the focus for large data sets is primarily on model fitting and comparison.

The CPANEL procedure is specifically designed to operate in SAS Viya and performs computations in multiple threads. The PANEL procedure executes in a single thread on a single machine.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CPANEL Procedure

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections “[Using CAS Sessions and CAS Engine Librefs](#)” on page 54 and “[Loading a SAS Data Set onto a CAS Server](#)” on page 55 in Chapter 4, “[Shared Concepts](#).”

The following DATA step creates the data table Electricity from the cost function data in Greene (1990). This DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref. The variable Production is the log of output in millions of kilowatt-hours, and the variable Cost is the log of cost in millions of dollars.

```
data mylib.Electricity;
  input firm year production cost @@;
datalines;
1 1955 5.36598 1.14867 1 1960 6.03787 1.45185
1 1965 6.37673 1.52257 1 1970 6.93245 1.76627
2 1955 6.54535 1.35041 2 1960 6.69827 1.71109
2 1965 7.40245 2.09519 2 1970 7.82644 2.39480
3 1955 8.07153 2.94628 3 1960 8.47679 3.25967
3 1965 8.66923 3.47952 3 1970 9.13508 3.71795
4 1955 8.64259 3.56187 4 1960 8.93748 3.93400
4 1965 9.23073 4.11161 4 1970 9.52530 4.35523
5 1955 8.69951 3.50116 5 1960 9.01457 3.68998
5 1965 9.04594 3.76410 5 1970 9.21074 4.05573
6 1955 9.37552 4.29114 6 1960 9.65188 4.59356
6 1965 10.21163 4.93361 6 1970 10.34039 5.25520
;
```

Consider the model

$$C_{it} = \beta_0 + \beta_1 P_{it} + v_i + e_{it} \text{ for } i = 1, \dots, N \text{ and } t = 1, \dots, T$$

where C_{it} represents cost, P_{it} represents production, v_i is the cross-sectional error component, and e_{it} is the error variance component.

If you assume that the cross-sectional effects are random, five possible estimators are available for the variance components. The VCOMP=FB option in the following statements uses the Fuller and Battese (1974) estimator to fit the model:

```
proc cpanel data = mylib.Electricity;
  id firm year;
  model cost = production / ranone vcomp = fb;
run;
```

The output of these statements is shown in [Output 11.1](#).

Figure 11.1 One-Way Random-Effects Estimation Results

The CPANEL Procedure
One-Way Random Effects (RanOne)
Fuller and Battese Variance Components
Dependent Variable: cost

Model Description			
Estimation Method		RanOne	
Variance Estimation		Model Based	
Data Set		ELECTRICITY	
Number of Observations		24	
Number of Cross Sections		6	
Time Series Length		4	

Fit Statistics			
SSE	0.4143	DFE	22
MSE	0.0188	Root MSE	0.1372
R-Square	0.9164		

Variance Component Estimates		
Source	Variance	Standard Deviation
Cross Sections	0.04109	0.202707
Error	0.015533	0.124632

Hausman Test For Random Effects			
Coefficients	DF	m Value	Pr > m
1	1	9.08	0.0026

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Pr > t
Intercept	1	-3.27307	0.4277	-7.65	<.0001
production	1	0.779469	0.0502	15.53	<.0001

Printed first is a report that provides the estimation method and various data counts. Fit statistics and variance components estimates are printed next. A Hausman specification test compares this model to its fixed-effects counterpart. Finally, the table of regression parameter estimates shows the estimates, standard errors, and t tests.

Syntax: CPANEL Procedure

The following statements are available in the CPANEL procedure:

```

PROC CPANEL < options > ;
  BY variables ;
  CLASS variable < (options) > ... < variable < (options) > > < / global-options > ;
  COMPARE < model-list > < / options > ;
  CORRELATED effects ;
  DISPLAY < table-list > < / options > ;
  DISPLAYOUT table-spec-list < / options > ;
  ENDOGENOUS effects < / option > ;
  ID cross-section-id < time-series-id > ;
  INSTRUMENTS effects < / option > ;
  MODEL response = < effects > < / options > ;
  OUTPUT OUT=libref.data-table < options > ;
  PREDETERMINED effects < / option > ;
  RESTRICT equation1 < , equation2... > ;
  TEST equation1 < , equation2... > ;

```

Functional Summary

Table 11.1 summarizes the statements and options that the CPANEL procedure supports.

Table 11.1 Functional Summary

Description	Statement	Option
Data Table Options		
Specifies the input data table	PROC CPANEL	DATA=
Prevents partitioning of data by cross sections	PROC CPANEL	NOPART
Specifies the name of an output SAS data table	OUTPUT	OUT=
Variable Role Statements		
Specifies BY-group processing	BY	
Specifies the classification variables	CLASS	
Specifies the cross section and time ID variables	ID	
Declares correlated variables or effects	CORRELATED	
Declares endogenous variables or effects	ENDOGENOUS	
Declares instrumental variables or effects	INSTRUMENTS	
Declares predetermined variables or effects	PREDETERMINED	
Printing Control Options		
Specifies the ODS tables to display	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	

Table 11.1 *continued*

Description	Statement	Option
Prints correlations of the estimates	MODEL	CORRB
Prints covariances of the estimates	MODEL	COVB
Suppress parameter labels from output tables	MODEL	NOLABEL
Suppresses printed output	PROC CPANEL	NOPRINT
Prints all available output	PROC CPANEL	PRINTALL
Prints fixed effects	MODEL	PRINTFIXED
Model Estimation Technique Options		
Specifies the Amemiya-MaCurdy model	MODEL	AMACURDY
Specifies the between-groups model	MODEL	BTWNG
Specifies the between-time-periods model	MODEL	BTWNT
Specifies the dynamic panel model via first-differencing GMM	MODEL	DYNDIFF
Specifies the dynamic panel model via system GMM	MODEL	DYNSYS
Specifies the one-way fixed-effects model via first-differencing	MODEL	FDONE
Specifies the one-way fixed-effects model	MODEL	FIXONE
Specifies the one-way fixed-effects model with respect to time	MODEL	FIXONETIME
Specifies the two-way fixed-effects model	MODEL	FIXTWO
Specifies the Hausman-Taylor model	MODEL	HTAYLOR
Specifies the between-groups model with instrumental variables	MODEL	IVBTWNG
Specifies the one-way fixed-effects model with instrumental variables	MODEL	IVFIXONE
Specifies the one-way fixed-effects model for time effects with instrumental variables	MODEL	IVFIXONETIME
Specifies the two-way fixed-effects model with instrumental variables	MODEL	IVFIXTWO
Specifies the generalized two-stage least squares model with instrumental variables	MODEL	IVG2SLS
Specifies the pooled regression model with instrumental variables	MODEL	IVPOOLED
Specifies the one-way random-effects model with instrumental variables	MODEL	IVRANONE
Specifies the two-way random-effects model with instrumental variables	MODEL	IVRANTWO
Specifies the pooled regression model	MODEL	POOLED
Specifies the one-way random-effects model	MODEL	RANONE
Specifies the two-way random-effects model	MODEL	RANTWO
Model Estimation Control Options		
Sets the number of AR(m) tests	MODEL	ARTESTS=

Table 11.1 *continued*

Description	Statement	Option
Specifies bias-corrected variances for two-step GMM	MODEL	BIASCORRECTED
Requests the clustered HCCME estimator for the covariance matrix	MODEL	CLUSTER
Sets the number of dependent variable lags	MODEL	DLAGS=
Specifies the generalized inverse type	MODEL	GINV=
Specifies one-step or two-step GMM	MODEL	GMM=
Requests the HAC estimator for the variance-covariance matrix	MODEL	HAC
Requests the HCCME estimator for the covariance matrix	MODEL	HCCME=
Limits the number of GMM instruments	MODEL	MAXBAND=
Suppresses the intercept term	MODEL	NOINT
Specifies robust variances estimator	MODEL	ROBUST
Specifies the method for the variance components estimator	MODEL	VCOMP=
Tests and Restrictions		
Specifies linear equality restrictions on the parameters	RESTRICT	
Performs tests of linear hypotheses	TEST	WALD, LM, LR
Model Comparison Statements		
Create tables that display side-by-side model comparisons	COMPARE	

PROC CPANEL Statement

PROC CPANEL <options> ;

The PROC CPANEL statement invokes the procedure. You can specify the following *options*:

DATA=*libref.data-table*

names the input data table for PROC CPANEL to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 465.

data-table specifies the name of the input data table.

NOPART

prevents repartitioning of the data. Normally, the CPANEL procedure redistributes the data table so that observations for each cross section are not divided among multiple machines. Repartitioning the data makes model computations more efficient but has a cost in memory and computing cycles that are associated with redistribution. Specifying the NOPART option leaves the data distributed as they are, at the expense of less efficient model computations.

NOPRINT

suppresses all printed output.

PRINTALL

prints all available output.

In addition, any of the following MODEL statement options can be specified in the PROC CPANEL statement: **CORRB**, **COVB**, **NOLABEL**, and **PRINTFIXED**. When specified in the PROC CPANEL statement, these options apply globally to every MODEL statement. For a complete description of each of these options, see the section “MODEL Statement” on page 479.

BY Statement

BY *variables* ;

You can specify a BY statement in PROC CPANEL to obtain separate analyses of observations in groups that are defined by the values of the BY variables. If you specify more than one BY statement, only the last one specified is used. For more information, see the discussion of BY-group processing in the “Grouping Data” section of *SAS Programmers Guide: Essentials*.

CLASS Statement

CLASS *variable* < (*options*) > . . . < *variable* < (*options*) > > < / *global-options* > ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. Table 11.2 summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section “CLASS Statement” on page 56 in Chapter 4, “Shared Concepts.”

Table 11.2 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable

COMPARE Statement

COMPARE <model-list> </options> ;

The COMPARE statement creates tables of side-by-side comparisons of parameter estimates and other model statistics. You can fit multiple models simultaneously by specifying multiple MODEL statements, and you can specify a COMPARE statement to create tables that compare the models.

The COMPARE statement creates two tables: the first table compares model fit statistics such as R-square and mean square error; the second table compares regression coefficients, their standard errors, and (optionally) *t* tests.

By default, comparison tables are created for all fitted models, but you can use the optional *model-list* to limit the comparison to a subset of the fitted models. The *model-list* consists of a set of model labels, as specified in the MODEL statement; for more information, see the section “MODEL Statement” on page 479. If a model does not have a label, you refer to it generically as “Model *i*,” where the corresponding model is the *i*th MODEL statement specified.

You can specify one or more COMPARE statements. The following code illustrates the use of the COMPARE statement:

```
proc cpanel data = mylib.a;
  id csid tsid;
  mod_one: model y = x1 x2 x3 / fixone;
  second: y = x1 x2 / fixone;
  model y = x1 x2 x3 x4 / ranone;
  compare;
  compare "second" "Model 3";
run;
```

The first COMPARE statement compares all three fitted models. The second COMPARE statement uses the generic “Model 3” to identify the third model and compares it to the second model.

You can specify the following *options* after a slash (/):

MSTAT (*mstat-list*)

specifies a list of model fit statistics to be displayed. A set of statistics is displayed by default, but you can use this option to specify a custom set of model statistics.

The *mstat-list* can contain one or more of the following keywords:

ALL	displays all model fit statistics. Not all statistics are appropriate for all models, and thus not always calculated. A blank cell in the table indicates that the statistic is not appropriate for that model.
DFE	displays the error degrees of freedom. This statistic is displayed by default.
F	displays the <i>F</i> statistic of the overall test for no fixed effects.
FNUMDF	displays the numerator degrees of freedom of the overall test for no fixed effects.
FDENDF	displays the denominator degrees of freedom of the overall test for no fixed effects.
M	displays the Hausman test <i>m</i> statistic.
MDF	displays the Hausman test degrees of freedom.

MSE	displays the model mean square error. This statistic is displayed by default.
NCS	displays the number of cross sections. This statistic is displayed by default.
NOBS	displays the number of observations. This statistic is displayed by default.
NONE	suppresses the table of model fit statistics when specified alone, and is ignored when specified with other options.
NTS	displays the maximum length of the time series. This statistic is displayed by default.
PROBF	displays the significance level of the overall test for no fixed effects.
PROBM	displays the significance level of the Hausman test.
RMSE	displays the model root mean square error.
RSQUARE	displays the model R-square fit statistic. This statistic is displayed by default.
SSE	displays the model sum of squares.
VARCS	displays the variance component that corresponds to cross sections in random-effects models.
VARERR	displays the variance component that corresponds to error in random-effects models.
VARTS	displays the variance component that corresponds to time series in random-effects models.

OUTPARM=libref.data-table

names an output data table to contain the data from the comparison table for parameter estimates, standard errors, and *t* tests. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 465.

OUTSTAT=libref.data-table

names an output data table to contain the data from the comparison table for model fit statistics, such as R-square and mean square error. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “Using CAS Sessions and CAS Engine Librefs” on page 465.

PSTAT (pstat-list)

specifies a list of parameter statistics to be displayed. By default, estimated regression coefficients and their standard errors are displayed. Use this option to specify a custom set of parameter statistics.

pstat-list can contain one or more of the following keywords:

ALL	displays all parameter statistics.
ESTIMATE	displays the estimated regression coefficient. This statistic is displayed by default.
NONE	suppresses the table of parameter statistics when specified alone, and is ignored when specified with other options.
STDERR	displays the standard error. This statistic is displayed by default.
PROBT	displays the significance level of the <i>t</i> test.

T displays the t statistic.

For a demonstration of the COMPARE statement, see [Example 11.2](#).

CORRELATED Statement

CORRELATED *effects* ;

The CORRELATED statement selects the subset of effects from the **MODEL** statement that are correlated with the individual (or cross-sectional) error term. This statement is valid only when you specify the **AMACURDY** or **HTAYLOR** model estimation method in the MODEL statement.

If you specify an *effect* in the CORRELATED statement but not in the MODEL statement, then the *effect* is added to the list of model effects and treated as correlated with the cross-sectional error term. If you have multiple MODEL statements, then each CORRELATED statement is associated with the MODEL statement that immediately precedes it.

The following statements fit a Hausman and Taylor (1981) model with model effects X1, X2, Z1, and Z2. The effects X2 and Z2 are correlated with the cross-sectional (firm-level) error term.

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / htaylor;
  correlated X2 Z2;
run;
```

You can also specify classification variables, interactions, and nested effects. For more information about constructing model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[ODS Table Names](#)” on page 532. A path is a table name that is prefixed with dot-separated grouping information. For example, a

SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying */tions/* selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying *!/tions/* selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

<i>key=value</i>	specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name.
<i>key</i>	specifies <i>key</i> as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 532. You cannot specify the ODS table named *OutputCasTables* in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

ENDOGENOUS Statement

ENDOGENOUS *effects* </ option> ;

The ENDOGENOUS statement declares a set of *effects* that are treated as endogenous during estimation, and is valid only when you perform either instrumental variables regression or dynamic panel estimation.

Instrumental Variables (IV) Regression

You perform instrumental variables (IV) regression by specifying one or more of the **IVBTWNG**, **IVFIXONE**, **IVFIXONETIME**, **IVFIXTWO**, **IVG2SLS**, **IVPOOLED**, **IVRANONE**, and **IVRANTWO** options in the **MODEL** statement.

When you use the ENDOGENOUS statement for IV regression, it selects the subset of effects from the **MODEL** statement that are endogenous—that is, the effects that are correlated with the observation-level error term.

If you specify an *effect* in the ENDOGENOUS statement but not in the **MODEL** statement, then the *effect* is added to the list of model effects and treated as endogenous. If you have multiple **MODEL** statements, then each ENDOGENOUS statement is associated with the **MODEL** statement that immediately precedes it.

The ENDOGENOUS statement is used in conjunction with the **INSTRUMENTS** statement to perform IV regression. The following statements perform IV fixed-effects regression with the model effects X1, X2, Z1, and Z2. The effects X2 and Z2 are endogenous, and G1 and G2 are external instruments.

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / ivfixone;
  endogenous X2 Z2;
  instruments G1 G2;
run;
```

Dynamic Panel Estimation

You perform dynamic panel estimation by specifying the **DYNDIFF** or **DYNSYS** option in the **MODEL** statement.

When you use the ENDOGENOUS statement in dynamic panel estimation, it specifies a set of variables whose instruments follow a prescribed form that is appropriate for endogenous regressors.

If you have multiple MODEL statements, then each ENDOGENOUS statement is associated with the MODEL statement that immediately precedes it.

You can specify the following *option* after a slash (/):

EQ=BOTH | DIFF | LEVEL

specifies which equations include the endogenous instruments. You can specify the following values:

- BOTH** includes the endogenous instruments in both the difference and level equations.
- DIFF** includes the endogenous instruments only in the difference equations.
- LEVEL** includes the endogenous instruments only in the level equations.

By default, EQ=BOTH.

The following statements perform dynamic panel estimation by using GMM-style instruments for the endogenous variable *Sales* and standard instruments for the exogenous variable *Price*. Both sets of instruments are included only in the difference equations.

```
proc cpanel data = mylib.a;
  id firm year;
  model Sales = Price / dyndiff;
  endogenous Sales / eq = diff;
  instruments Price / eq = diff;
run;
```

For both IV regression and dynamic panel estimation, you can also specify classification variables, interactions, and nested effects in the ENDOGENOUS statement. For more information about constructing model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

ID Statement

ID *cross-section-id* < *time-series-id* > ;

The ID statement specifies variables in the input data table that identify the cross section and time period for each observation. Sometimes estimation does not require a time variable, in which case specifying the *time-series-id* variable is optional.

INSTRUMENTS Statement

INSTRUMENTS *effects* </ *option* > ;

The INSTRUMENTS statement specifies instrumental variables and effects. It is valid only when you perform either instrumental variables regression or dynamic panel estimation.

Instrumental Variables (IV) Regression

You perform instrumental variables (IV) regression by specifying one or more of the [IVBTWNG](#), [IVFIXONE](#), [IVFIXONETIME](#), [IVFIXTWO](#), [IVG2SLS](#), [IVPOOLED](#), [IVRANONE](#), and [IVRANTWO](#) options in the MODEL statement.

The effects that you specify in the INSTRUMENTS statement are auxiliary effects external to those that you specify in the MODEL statement. If you have multiple MODEL statements, then each INSTRUMENTS statement is associated with the MODEL statement that immediately precedes it.

The INSTRUMENTS statement is used in conjunction with the ENDOGENOUS statement to perform IV regression. The following statements perform IV fixed-effects regression with the model effects X1, X2, Z1, and Z2. The effects X2 and Z2 are endogenous, and G1 and G2 are external instruments.

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / ivfixone;
  endogenous X2 Z2;
  instruments G1 G2;
run;
```

Dynamic Panel Estimation

You perform dynamic panel estimation by specifying the [DYNDIFF](#) or [DYNSSYS](#) options in the MODEL statement.

When you use the INSTRUMENTS statement in dynamic panel estimation, it specifies a set of variables to be included as standard instruments.

If you have multiple MODEL statements, then each INSTRUMENTS statement is associated with the MODEL statement that immediately precedes it.

You can specify the following *option* after a slash (/):

EQ=BOTH | DIFF | LEVEL

specifies which equations include the standard instruments. You can specify the following values:

- BOTH** includes the standard instruments in both the difference and level equations.
- DIFF** includes the standard instruments only in the difference equations.
- LEVEL** includes the standard instruments only in the level equations.

By default, EQ=BOTH.

The following statements perform dynamic panel estimation by using GMM-style instruments for the endogenous variable Sales and standard instruments for the exogenous variable Price. Both sets of instruments are included only in the difference equations.

```

proc cpanel data = mylib.a;
  id firm year;
  model Sales = Price / dyndiff;
  endogenous Sales / eq = diff;
  instruments Price / eq = diff;
run;

```

For both IV regression and dynamic panel estimation, you can also specify classification variables, interactions, and nested effects in the INSTRUMENTS statement. For more information about constructing model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

MODEL Statement

MODEL *response* = < *effects* > < / *options* > ;

The MODEL statement specifies the regression model, the error structure that is assumed for the regression residuals, and the estimation technique to be used. The response variable (*response*) on the left side of the equal sign is regressed on the independent variables (*effects*), which are listed after the equal sign. You can specify any number of MODEL statements. For each MODEL statement, you can specify only one *response*.

For information about constructing the model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

You can label models. Model labels are used in the printed output to identify the results for different models. If you do not specify a label, the model is referred to by numerical order wherever necessary. You can label models by prefixing the MODEL statement by a label followed by a colon as follows:

label: **MODEL** ...;

The MODEL statement supports many options, some more specific than others. [Table 11.3](#) summarizes the *options* available in the MODEL statement. These are subsequently discussed in detail in the order in which they are presented in the table.

Table 11.3 Summary of MODEL Statement Options

Option	Description
Estimation Technique Options	
AMACURDY	Fits a one-way model by using the Amemiya-MaCurdy estimator
BTWNG	Fits the between-groups model
BTWNT	Fits the between-time-periods model
DYNDIFF	Fits a dynamic panel model by using first-differences GMM
DYNSYS	Fits a dynamic panel model by using system GMM
FDONE	Fits a one-way model by using first differences
FIXONE	Fits a one-way fixed-effects model
FIXONETIME	Fits a one-way fixed-effects model for time effects
FIXTWO	Fits a two-way fixed-effects model

Table 11.3 *continued*

Option	Description
HTAYLOR	Fits a one-way model by using the Hausman-Taylor estimator
IVBTWNG	Fits a between-groups regression model by using instrumental variables
IVFIXONE	Fits a one-way fixed-effects model by using instrumental variables
IVFIXONETIME	Fits a one-way time fixed-effects model for time effects by using instrumental variables
IVFIXTWO	Fits a two-way fixed-effects model by using instrumental variables
IVG2SLS	Fits a generalized two-stage least squares model by using instrumental variables
IVPOOLED	Fits the pooled regression model by using instrumental variables
IVRANONE	Fits a one-way random-effects model by using instrumental variables
IVRANTWO	Fits a two-way random-effects model by using instrumental variables
POOLED	Fits the pooled regression model
RANONE	Fits a one-way random-effects model
RANTWO	Fits a two-way random-effects model
Estimation Control Options	
BIASCORRECTED	Computes bias-corrected two-step GMM variances for instrumental variables models and dynamic panel models
GMM=	Specifies one-step or two-step GMM for instrumental variables models and dynamic panel models
NOINT	Suppresses the intercept
VCOMP=	Specifies the type of variance component estimation for random-effects estimation
Dynamic Panel Estimation Options	
ARTESTS=	Specifies the maximum lag of $AR(m)$ tests
DLAGS=	Specifies the number of dependent variable lags to include
GINV=	Specifies the generalized inverse method
MAXBAND=	Limits the number of instruments
Alternative Variances Options	
CLUSTER	Corrects covariance for intracluster correlation
HAC	Specifies a heteroscedasticity- and autocorrelation-consistent (HAC) covariance

Table 11.3 *continued*

Option	Description
HCCME=	Specifies a heteroscedasticity-corrected covariance matrix estimator (HCCME)
MAXBAND=	Limits the number of instruments
ROBUST	Computes robust variances
Printed Output Options	
CORRB	Prints the parameter correlation matrix
COVB	Prints the parameter covariance matrix
NOLABEL	Suppresses variable labels
PRINTFIXED	Estimates and prints the fixed effects

You can specify the following *options* after a slash (/).

Estimation Technique Options

These options specify the assumed error structure and estimation method. You can specify more than one option, in which case the analysis is repeated for each. The default is FIXONE (one-way fixed effects).

All estimation methods are described in detail in the section “[Details: CPANEL Procedure](#)” on page 491.

AMACURDY

requests Amemiya-MaCurdy estimation for a model that has correlated individual (cross-sectional) effects. You specify the correlated effects by using the CORRELATED statement.

BTWNG

estimates a between-groups model.

BTWNT

estimates a between-time-periods model.

DYNDIFF

estimates a dynamic panel by using the generalized method of moments (GMM) on equations that are formed by first differencing.

DYNSYS

estimates a dynamic panel by using GMM on the system that combines first-differenced equations and level equations.

FDONE

estimates a one-way model by using first-differenced methods.

FIXONE

estimates a one-way fixed-effects model that corresponds to cross-sectional effects only.

FIXONETIME

estimates a one-way fixed-effects model that corresponds to time effects only.

FIXTWO

estimates a two-way fixed-effects model.

HTAYLOR

requests Hausman-Taylor estimation for a model that has correlated individual (cross-sectional) effects. You specify the correlated effects by using the `CORRELATED` statement.

IVBTWNG

requests instrumental variables regression for between-groups estimation for a model that has endogenous effects. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVFIXONE

requests instrumental variables regression for one-way fixed-effects estimation for a model that has endogenous effects. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVFIXONETIME

requests instrumental variables regression for one-way time fixed-effects estimation for a model that has endogenous effects. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVFIXTWO

requests instrumental variables regression for two-way fixed-effects estimation for a model that has endogenous effects. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVG2SLS

requests instrumental variables regression for generalized two-stage least squares estimation for a model that has endogenous effects. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVPOOLED

requests instrumental variables regression for pooled regression. You specify the endogenous effects by using the `ENDOGENOUS` statement, and you specify external instruments by using the `INSTRUMENTS` statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVRANONE

requests instrumental variables regression for one-way random-effects estimation for a model that has endogenous effects. You specify the endogenous effects by using the **ENDOGENOUS** statement, and you specify external instruments by using the **INSTRUMENTS** statement. You can choose to use two-stage least squares or GMM to estimate the model.

IVRANTWO

requests instrumental variables regression for two-way random-effects estimation for a model that has endogenous effects. You specify the endogenous effects by using the **ENDOGENOUS** statement, and you specify external instruments by using the **INSTRUMENTS** statement. You can choose to use two-stage least squares or GMM to estimate the model.

POOLED

estimates a pooled (OLS) model.

RANONE

estimates a one-way random-effects model.

RANTWO

estimates a two-way random-effects model.

Estimation Control Options

These options define parameters that control the estimation and can be specific to the chosen technique (for example, how to estimate variance components in a random-effects model).

BIASCORRECTED

computes the bias-corrected covariance matrix of the two-step generalized method of moments (GMM) estimator. This statement is valid only when you perform either dynamic panel estimation or instrumental variables regression.

CLUSTER

specifies the cluster correction for the covariance matrix. You can specify this option when you specify **HCCME=0, 1, 2, or 3**.

GMM=ONESTEP | TWOSTEP

specifies the number of GMM stages to use in the estimation. This statement is valid only when you perform either dynamic panel estimation or instrumental variables regression.

You can specify the following values:

ONESTEP	uses one-step GMM, which is computationally simple but dependent on model assumptions.
TWOSTEP	uses two-step GMM, which is computationally intensive but more robust to violations of model assumptions.

By default, **GMM=ONESTEP**.

The following statements perform two-step GMM in a dynamic panel model, which is requested by the **DYNDIFF** option in the **MODEL** statement. You can use similar statements for a dynamic panel estimation that uses a full system of difference and level equations by specifying the **DYNSYS** option

instead of the DYNDIFF option in the MODEL statement. The endogenous variable is *Sales*, and the GMM-style instruments is the predetermined variable *Price*. Both sets of instruments are included only in the difference equations.

```
proc cpanel data = mylib.a;
  id firm year;
  model Sales = Price / dyndiff GMM = TWOSTEP;
  endogenous Sales / eq = diff;
  predetermined Price / eq = diff;
run;
```

The following statements perform two-step GMM in an instrumental variables model. The endogenous variables are *X2* and *Z2*, and the external instruments are *G1* and *G2*.

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / ivfixone GMM = TWOSTEP;
  endogenous X2 Z2;
  instruments G1 G2;
run;
```

The IVFIXONE option in the MODEL statement requests IV one-way fixed-effects estimation. You can request other types of IV estimation by specifying IVBTWNG, IVFIXONETIME, IVFIXTWO, IVG2SLS, IVPOOLED, IVRANONE, or IVRANTWO instead of IVFIXONE in the MODEL statement.

HAC <(options)>

specifies the heteroscedasticity- and autocorrelation-consistent (HAC) covariance matrix estimator. This option is not available for between-groups or between-time-periods models, and cannot be combined with the HCCME= option.

You can specify the following *options* within parentheses and separated by spaces:

ADJUSTDF

makes a small-sample adjustment to the degrees of freedom in the covariance calculation.

BANDWIDTH=*number* | *method*

specifies the fixed bandwidth value or bandwidth selection method to be used in the kernel function. You can specify either a fixed value (*number*) or one of the *methods* listed after *number*.

number

specifies a fixed value of the bandwidth parameter.

ANDREWS | **AN**

specifies the Andrews (1991) bandwidth selection method.

NEWWEYWEST<(C=number)> | NW <(C=number)>

specifies the bandwidth selection method of Newey and West (1994) You can also specify *C=number* to calculate the lag selection parameter; by default, *C=12*.

SAMPLESIZE<(options)> | SS<(options)>

calculates the bandwidth according to the following equation based on the sample size,

$$b = \gamma T^r + c$$

where *b* is the bandwidth parameter; *T* is the sample size; and γ , *r*, and *c* are values that you specify using the following *options* within parentheses and separated by spaces:

CONSTANT=number

specifies the constant *c* in the equation. By default, *CONSTANT=0.5*.

GAMMA=number

specifies the coefficient γ in the equation. By default, *GAMMA=0.75*.

INTSS

specifies that the bandwidth parameter be an integer; that is, $b = \lfloor \gamma T^r + c \rfloor$, where $\lfloor x \rfloor$ denotes the largest integer less than or equal to *x*.

RATE=number

specifies the growth rate *r* in the equation. By default, *RATE=0.3333*.

By default, *BANDWIDTH=ANDREWS*.

KERNEL=BARTLETT | PARZEN | QS | TH | TRUNCATED

specifies the type of kernel function. You can specify the following values:

BARTLETT	specifies the Bartlett kernel function.
PARZEN	specifies the Parzen kernel function.
QS	specifies the quadratic spectral kernel function.
TH	specifies the Tukey-Hanning kernel function.
TRUNCATED	specifies the truncated kernel function.

By default, *KERNEL=QS*.

KERNELLB=number

specifies the lower bound of the kernel weight value. Any kernel weight less than *number* is regarded as 0, which accelerates the calculation in large samples, especially for the quadratic spectral kernel function. By default, *KERNELLB=0*.

PREWHITENING

requests prewhitening in the covariance calculation.

The following statements perform one-way fixed-effects estimation by using the Newey-West bandwidth and a Bartlett kernel based on a prewhitened gradient vector:

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / ivfixone gmm=twostep
  hac(bandwidth=neweywest(c=12) kernel=bartlett prewhitening);
run;
```

HCCME=0 | 1 | 2 | 3

specifies the type of adjustment to the HCCME covariance matrix. You can specify the values 0 through 3, which indicate the type of covariance adjustment.

NOINT

suppresses the intercept parameter from the model.

ROBUST

computes the robust covariance matrix. This option can be applied to dynamic panel models, instrumental variables regression models, and static panel models. For dynamic panel models and instrumental variables regression models, the option provides heteroscedasticity-corrected standard errors according to the GMM estimation method. The following statements perform IV fixed-effects regression with robust standard errors:

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / ivfixone gmm=twostep robust;
  endogenous X2 Z2;
  instruments G1 G2;
run;
```

For static panel models, this option produces cross-sectional clustered standard errors when HCCME=0. The following statements perform one-way fixed-effects regression with clustered standard errors:

```
proc cpanel data = mylib.a;
  id firm year;
  model Y = X1 X2 Z1 Z2 / fixone robust;
run;
```

VCOMP=FB | NL | SA | WH | WK

specifies the type of variance component estimate to use. You can specify the following values:

- FB** uses the Fuller-Battese method.
- NL** uses the Nerlove method.
- SA** uses the Swamy-Arora method.
- WH** uses the Wallace-Hussain method.
- WK** uses the Wansbeek-Kapteyn method.

By default, VCOMP=SA.

Dynamic Panel Estimation Options

These options are specific to dynamic panel estimation, which you obtain by specifying the DYNDIFF or DYNSSYS option in the MODEL statement.

ARTESTS=integer

specifies the maximum order of the test for the presence of autoregression (AR) effects. By default, ARTESTS=2.

DLAGS=integer

specifies the number of dependent-variable lags to use as regressors. By default, DLAGS=1.

GINV=G2 | G4

specifies what type of generalized inverse to use. You can specify the following values:

G2 uses the G2 generalized inverse.

G4 uses the G4 generalized inverse.

The difference between G2 and G4 becomes evident when you invert singular matrices. The G2 generalized inverse drops rows and columns from singular matrices to produce a viable inverse. The G4 inverse, on the other hand, is the Moore-Penrose generalized inverse, which averages the variance effects between collinear rows. The G4 inverse is usually more stable, but it is computationally intensive. By default, GINV=G2. If you have trouble reproducing published results, often the solution is to switch to GINV=G4.

MAXBAND=integer

if specified, sets the maximum number of GMM-style instruments per observation, for each variable. Because the number of GMM-style instruments grows quadratically with the number of time periods, this option makes estimation more feasible when you have many time periods.

Printed Output Options

These options alter how results are presented.

CORRB

prints the matrix of estimated correlations between the parameter estimates.

COVB

prints the matrix of estimated covariances between the parameter estimates.

NOLABEL

suppresses variable labels from the printed output.

PRINTFIXED

estimates and prints the fixed effects in models where they would normally be absorbed within the estimation.

OUTPUT Statement

OUTPUT OUT=*libref.data-table* < options > ;

The OUTPUT statement creates a data table that contains observationwise statistics that PROC CPANEL computes after fitting the model. In order to avoid data duplication for large data tables, only the identification and dependent variables are included in the output data table unless you specify additional variables in the **COPYVAR=** option. To avoid further data duplication, the OUTPUT statement is allowed only with MODEL statements that request a single estimation. If you have multiple MODEL statements, then each OUTPUT statement is associated with the MODEL statement that immediately precedes it.

You must specify the following option:

OUT=*libref.data-table*

names the output data table for PROC CPANEL to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

<i>libref</i>	refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about <i>libref</i> , see the section “Using CAS Sessions and CAS Engine Librefs” on page 465.
---------------	--

<i>data-table</i>	specifies the name of the output data table.
-------------------	--

You can also specify the following options:

COPYVAR=*variable*

COPYVARS=(*variables*)

transfers one or more *variables* from the input data table to the output data table.

PREDICTED=*name*

P=*name*

writes the predicted values to the output data table.

RESIDUAL=*name*

R=*name*

writes the residuals to the output data table.

PREDETERMINED Statement

PREDETERMINED *effects* < / *option* > ;

The PREDETERMINED statement specifies a set of variables whose instruments follow a prescribed form that is appropriate for predetermined regressors and is valid only when you perform dynamic panel estimation by specifying the **DYNDIFF** or **DYNSYS** option in the MODEL statement.

If you have multiple MODEL statements, then each PREDETERMINED statement is associated with the MODEL statement that immediately precedes it.

You can specify the following *option* after a slash (/):

EQ=BOTH | DIFF | LEVEL

specifies which equations include the predetermined instruments. You can specify the following values:

BOTH includes the predetermined instruments in both the difference and level equations.

DIFF includes the predetermined instruments only in the difference equations.

LEVEL includes the predetermined instruments only in the level equations.

By default, EQ=BOTH.

The following statements perform dynamic panel estimation by using GMM-style instruments for the endogenous variable Sales and GMM-style instruments for the predetermined variable Price. Both sets of instruments are included only in the difference equations.

```
proc cpanel data = mylib.a;
  id firm year;
  model Sales = Price / dyndiff;
  endogenous Sales / eq = diff;
  predetermined Price / eq = diff;
run;
```

You can also specify classification variables, interactions, and nested effects in the PREDETERMINED statement. For more information about constructing model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

RESTRICT Statement

RESTRICT *equation* < , *equation2* . . . > ;

The RESTRICT statement specifies linear equality restrictions on the parameters in the previous MODEL statement. There can be as many unique restrictions as the number of parameters in the preceding MODEL statement. Multiple RESTRICT statements are understood as joint restrictions on a model’s parameters. Restrictions on the intercept are obtained by the use of the INTERCEPT keyword. RESTRICT statements before the first MODEL statement are automatically associated with the first MODEL statement, in addition to any RESTRICT statements that follow it but precede subsequent MODEL statements.

Currently, only linear equality restrictions are permitted in PROC CPANEL. Tests and restriction expressions can be composed of only algebraic operations that involve the addition symbol (+), subtraction symbol (–), and multiplication symbol (*).

The following statements illustrate the use of the RESTRICT statement:

```
proc cpanel data = mylib.a;
  id csid tsid;
  model y = x1 x2 x3;
  restrict x1 = 0, x2 * .5 + 2 * x3 = 0;
  restrict intercept = 1;
run;
```

If you are fitting a dynamic panel model, you can place restrictions on lags of the dependent variable by referencing the name of the dependent variable, followed by an underscore and the lag order. For example:

```
proc cpanel data = mylib.a;
  model sales = price / dyndiff;
  restrict sales_1 = 0.5;
run;
```

Note that a RESTRICT statement cannot include a division sign in its formulation.

TEST Statement

TEST *equation <, equation2... > < /options> ;*

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Like RESTRICT statements, TEST statements before the first MODEL statement are automatically associated with the first MODEL statement, in addition to any TEST statements that follow it but precede subsequent MODEL statements. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. The INTERCEPT keyword refers to the coefficient of the intercept.

You can specify the following *options* after a slash (/):

ALL

specifies Lagrange multiplier, likelihood ratio, and Wald tests.

LM

specifies the Lagrange multiplier test.

LR

specifies the likelihood ratio test.

WALD

specifies the Wald test.

The Wald test is performed by default.

The following statements illustrate the use of the TEST statement:

```
proc cpanel data = mylib.a;
  id csid tsid;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 / all;
  test intercept = 0, x3 = 0;
run;
```

The first test investigates the joint hypothesis that $\beta_1 = 0$ and $0.5\beta_2 + 2\beta_3 = 0$.

Currently, only linear equality restrictions and tests are permitted in PROC CPANEL. Tests and restriction expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (−), and multiplication symbol (*).

If you are fitting a dynamic panel model, you can perform tests on lags of the dependent variable by referencing the name of the dependent variable, followed by an underscore and the lag order. For example:

```
proc cpanel data = mylib.a;
  model sales = price / dyndiff;
  test sales_1 = 0.5 / wald;
run;
```

When you use the TEST statement along with the MODEL statement options [AMACURDY](#), [DYNDIFF](#), [DYNSSYS](#), [HTAYLOR](#), [IVBTWNG](#), [IVFIXONE](#), [IVFIXONETIME](#), [IVFIXTWO](#), [IVG2SLS](#), [IVPOOLED](#), [IVRANONE](#), and [IVRANTWO](#), only the Wald test is available.

Details: CPANEL Procedure

Specifying the Input Data

Panel data are identified by both a cross section identification (ID) variable and a time variable. Suppose that cross sections are identified by the variable *State* and time periods are identified by the variable *Date*. You specify the cross section and time series variables in an ID statement. The following statements show the appropriate syntax:

```
proc panel data = mylib.a;
  id State Date;
  model ...;
run;
```

For some estimation strategies (such as one-way fixed effects), time is not relevant to the estimation. In these cases, specifying the time variable is optional. The CPANEL procedure alerts you if do not specify a time variable when one is required.

When taking lags or first differences, the CPANEL procedure determines that observations are adjacent in time only if their time values are exactly one unit apart. For this reason, you should index time by using a variable that contains consecutive integers.

PROC CPANEL performs its estimations regardless of how the data are partitioned logically across machines, but it might temporarily repartition the data to perform computations more efficiently. You can specify the

NOPART option in the PROC CPANEL statement to bypass this repartitioning, at the expense of slower execution.

Specifying the Regression Model

The CPANEL procedure is similar to other regression procedures in SAS software. Suppose you want to regress the variable *Y* on regressors *X1* and *X2*. You specify the dependent variable first, followed by an equal sign, followed by the list of regression variables, as shown in the following statements:

```
proc cpanel data mylib.a;
  id state date;
  model y = x1 x2;
run;
```

One advantage of using PROC CPANEL is that you can incorporate a model for the structure of the error terms. It is important to consider what type of model is appropriate for your data and to specify the corresponding option in the MODEL statement. The following model estimation options are supported: POOLED, BTWNG, BTWNT, FIXONE, FDONE, FIXTWO, RANONE, RANTWO, HTAYLOR, AMACURDY, IVPOOLED, IVBTWNG, IVFIXONE, IVFIXONETIME, IVFIXTWO, IVG2SLS, IVRANONE, IVRANTWO, DYNDIFF, and DYN SYS. The methods that underlie these estimation options are described, in order, beginning with the section “[Pooled Regression \(POOLED Option\)](#)” on page 494.

The following statements fit a one-way random-effects model with variance components estimated by the Fuller-Battese (FB) method:

```
proc cpanel data mylib.a;
  id State Date;
  model Y = X1 X2 / ranone vcomp = fb;
run;
```

You can specify more than one estimation option in the MODEL statement, and the analysis is repeated for each specified method. You can use multiple MODEL statements to estimate different regression models or to estimate the same model by different methods.

You can also specify classification variables, interactions, and nested effects, as demonstrated by the following statements:

```
proc cpanel data mylib.a;
  id State Date;
  class C1 C2 C3;
  model Y = X1 X2 C1 C2(C1) C3 C1*C3 / ranone vcomp = fb;
run;
```

For more information about constructing model effects, see the section “[Specification and Parameterization of Model Effects](#)” on page 91 in Chapter 4, “[Shared Concepts](#).”

Missing Values

Any observation in the input data table that has a missing value for the cross-section ID, time series ID, dependent variable, or any model effect is ignored by PROC CPANEL when it fits the model.

If there are observations in your data where only the dependent variable is missing, you can still compute predicted values for these observations and store them in an output data table by using the OUTPUT statement.

Unbalanced Data

Unbalanced data occur when not all time values are observed for all cross sections or, when time is not part of the estimation, the cross sections are not all the same size.

Whether the data are unbalanced by design or because of missing values, almost all the methods supported by the CPANEL procedure take proper account of the unbalanced data. The one exception is the AMACURDY method, which is suitable only for balanced data.

Common Notation

This section presents notation that is common to all subsequent sections. Consider the panel regression:

$$y_{it} = \alpha + \sum_{k=1}^K x_{itk} \beta_k + u_{it} \quad i = 1, \dots, N; t = 1, \dots, T_i$$

The total number of observations is $M = \sum_{i=1}^N T_i$. For balanced data, $T_i = T$ for all i . For unbalanced data, define T to be the number of unique time periods.

The exact representation of u_{it} and the underlying assumptions depend on the estimation method.

In matrix notation the model is

$$y_{it} = \alpha + \mathbf{x}_{it} \boldsymbol{\beta} + u_{it}$$

where $\mathbf{x}_{it}$ is a $1 \times K$ row vector of independent variables and $\boldsymbol{\beta}$ is the $K \times 1$ vector of coefficients. Let $\mathbf{y}$ and $\mathbf{X}$ be matrices that are formed by arranging the dependent and independent variables by cross section, and by time within each cross section. Let $\mathbf{X}_\alpha$ be the $\mathbf{X}$ matrix augmented by a first column of ones, which corresponds to the intercept term α .

Define the following utility matrices:

$\mathbf{I}_p$ is an identity matrix of dimension p .

$\mathbf{j}_p$ is a $p \times 1$ column vector of ones.

$\mathbf{J}_p = \mathbf{j}_p \mathbf{j}_p'$ is a matrix of ones of dimension p .

$\bar{\mathbf{J}}_p = p^{-1} \mathbf{J}_p$.

$$\mathbf{E}_p = \mathbf{I}_p - \bar{\mathbf{J}}_p.$$

In the following sections, the panel data are assumed to be unbalanced unless otherwise indicated. If the data are balanced, the formulas reduce appropriately.

Pooled Regression (POOLED Option)

You perform pooled regression by specifying the POOLED option in the MODEL statement. Pooled regression is standard ordinary least squares (OLS) regression without any cross-sectional or time effects. The error structure is simply $u_{it} = e_{it}$, where the e_{it} are independently and identically distributed (iid) with zero mean and variance σ_e^2 .

Between-Groups Regression (BTWNG and BTWNT Options)

You perform between-groups regression by specifying the BTWNG option in the MODEL statement. When the data are balanced, between-groups regression is ordinary least squares (OLS) regression performed on data that have been collapsed into cross-sectional means. When the data are unbalanced, the regression is weighted to assign more importance to larger cross sections. The cross-sectional means are multiplied by the weighting factor $w_i = \sqrt{T_i/\bar{T}}$, where $\bar{T} = M/N$ is the average cross section size.

The BTWNT option works similarly, except that the data are collapsed by time period instead of by cross section.

One-Way Fixed-Effects Model (FIXONE and FIXONETIME Options)

You perform one-way fixed-effects estimation by specifying the FIXONE option in the MODEL statement. The error structure for the one-way fixed-effects model is

$$u_{it} = v_i + e_{it}$$

where the v_i are nonrandom parameters that are restricted to sum to 0, and the e_{it} are iid with zero mean and variance σ_e^2 .

The fixed-effects model can be estimated by ordinary least squares (OLS), treating the v_i as coefficients on dummy variables that identify the cross sections. However, when N is large, you might want to estimate only β and not v_i .

Let $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$. The matrix $\mathbf{Q}_0$ represents the *within transformation*, the conversion of the raw data to deviations from a cross section's mean. Let $\mathbf{X}_w = \mathbf{Q}_0\mathbf{X}$ and $\mathbf{y}_w = \mathbf{Q}_0\mathbf{y}$. The within estimator of β is

$$\hat{\beta}_w = (\mathbf{X}_w' \mathbf{X}_w)^{-1} \mathbf{X}_w' \mathbf{y}_w$$

The previous estimation does not involve the intercept term because $\hat{\beta}_w$ is the same whether or not the intercept α is included in the model.

Standard errors, t statistics, and fit statistics such as mean square error (MSE) are all equivalent to those obtained from OLS regression of $\mathbf{y}_w$ on $\mathbf{X}_w$. The only exception is the error degrees of freedom, which equals $M - N - K$ to account for the tacit estimation of the N fixed effects.

The estimate of the intercept is

$$\hat{\alpha} = \bar{y}_{..} - \bar{x}_{..}\hat{\beta}_w$$

where $\bar{y}_{..}$ is the overall mean of y_{it} and $\bar{x}_{..}$ is the overall mean of x_{it} .

Fixed effects are not estimated as part of the regression, but they can be obtained by specifying the PRINTFIXED option in the MODEL statement. Each fixed effect is estimated as

$$\hat{v}_i = \bar{y}_{i.} - \bar{x}_{i.}\hat{\beta}_w$$

where $\bar{y}_{i.}$ and $\bar{x}_{i.}$ are cross-sectional means.

Variance estimates of $\hat{\alpha}$ and $\hat{v}_i$ are obtained by the delta method. If you specify the NOINT option, then the $\hat{v}_i$ are shifted to absorb $\hat{\alpha}$.

The FIXONETIME option works similarly, except that the data are grouped by time period instead of by cross section.

One-Way Fixed-Effects Model, First Differencing (FDONE Option)

You perform one-way fixed-effects estimation via first differencing by specifying the FDONE option in the MODEL statement. The method of first differencing offers an alternative to the within estimator $\hat{\beta}_w$. Consider the following one-way fixed-effects model:

$$y_{it} = \alpha + x_{it}\beta + v_i + e_{it}$$

For this model, the fixed effects are removed by subtracting first-order lags from both sides of the equation:

$$y_{it} - y_{i,t-1} = (x_{it} - x_{i,t-1})\beta + (e_{it} - e_{i,t-1})$$

Define $\Delta y_{it} = y_{it} - y_{i,t-1}$ and $\Delta x_{it} = x_{it} - x_{i,t-1}$, for $i = 1, \dots, N$ and $t = 2, \dots, T_i$. You obtain the first-differenced estimator, $\hat{\beta}_d$, and its variance by performing OLS regression of Δy_{it} on Δx_{it} .

You cannot obtain the error variance directly from the OLS regression because that regression is based on the differenced residual $e_{it} - e_{i,t-1}$. Instead, you can estimate σ_e^2 by $\hat{\sigma}_e^2 = \text{SSE}/(M - N - K)$, where

$$\text{SSE} = \sum_{i=1}^N \sum_{t=1}^{T_i} (y_{it} - x_{it}\hat{\beta}_d - \hat{v}_i)^2$$

and $\hat{v}_i = \bar{y}_{i.} - \bar{x}_{i.}\hat{\beta}_d$.

Estimation and inference for α and v_i are identical to that described in the section “One-Way Fixed-Effects Model (FIXONE and FIXONETIME Options)” on page 494, with $\hat{\beta}_w$ replaced by $\hat{\beta}_d$.

Two-Way Fixed-Effects Model (FIXTWO Option)

You perform two-way fixed-effects estimation by specifying the `FIXTWO` option in the `MODEL` statement. The error specification for the two-way fixed-effects model is

$$u_{it} = v_i + \lambda_t + e_{it}$$

where the v_i and λ_t are nonrandom parameters to be estimated. Assume the identifiability restriction $\sum_t \lambda_t = 0$.

Estimation is similar to that for one-way fixed effects, for which a within transformation is used to convert the problem to OLS regression. For two-way models under the general case of unbalanced data, the within transformation is more complex.

Following Wansbeek and Kapteyn (1989) and Baltagi (2013, sec. 9.4), let $\mathbf{X}^*$ and $\mathbf{y}^*$ be versions of $\mathbf{X}$ and $\mathbf{y}$ whose rows are sorted by time period, and by cross section within each time period. With the data sorted in this manner, define $\mathbf{D}_N$ to be the $M \times N$ design matrix for cross sections. Each row of $\mathbf{D}_N$ contains a 1 in the column that corresponds to that observation's cross section, and 0s in the remaining columns. Similarly, define $\mathbf{D}_T$ to be the $M \times T$ design matrix for time periods. In balanced data, $\mathbf{D}_N = \mathbf{j}_T \otimes \mathbf{I}_N$ and $\mathbf{D}_T = \mathbf{I}_T \otimes \mathbf{j}_N$.

Define the following:

$$\begin{aligned} \Delta_N &= \mathbf{D}_N' \mathbf{D}_N & (N \times N) \\ \Delta_T &= \mathbf{D}_T' \mathbf{D}_T & (T \times T) \\ \mathbf{A} &= \mathbf{D}_T' \mathbf{D}_N & (T \times N) \\ \bar{\mathbf{D}} &= \mathbf{D}_T - \mathbf{D}_N \Delta_N^{-1} \mathbf{A}' & (M \times T) \\ \mathbf{Q} &= \Delta_T - \mathbf{A} \Delta_N^{-1} \mathbf{A}' & (T \times T) \\ \mathbf{P} &= \mathbf{I}_M - \mathbf{D}_N \Delta_N^{-1} \mathbf{D}_N' - \bar{\mathbf{D}} \mathbf{Q}^{-1} \bar{\mathbf{D}}' & (M \times M) \end{aligned}$$

The matrix $\mathbf{P}$ provides the two-way within transformation. If the data are balanced, this amounts to transforming any data value z_{it} to $z_{it} - \bar{z}_{i.} - \bar{z}_{.t} + \bar{z}_{..}$.

Applying the two-way within transformation means that you can use OLS regression of $\mathbf{P}\mathbf{y}^*$ on $\mathbf{P}\mathbf{X}^*$ to obtain $\hat{\boldsymbol{\beta}}_f$, $\text{Var}(\hat{\boldsymbol{\beta}}_f)$, and fit statistics such as mean-square error (MSE), provided that you adjust the error degrees of freedom to equal $M - N - T - K + 1$.

Define the residual vector $\mathbf{r}^* = \mathbf{y}^* - \mathbf{X}^* \hat{\boldsymbol{\beta}}_f$. Estimates of the time effects are $\hat{\boldsymbol{\lambda}} = \mathbf{Q}^{-1} \bar{\mathbf{D}}' \mathbf{r}^*$, and estimates of the cross-sectional effects are $\hat{\mathbf{v}} = (\Theta_1 - \Theta_2 + \Theta_3) \mathbf{r}^*$, where

$$\begin{aligned} \Theta_1 &= \Delta_N^{-1} \mathbf{D}_N' \\ \Theta_2 &= \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{D}_T' \\ \Theta_3 &= \Delta_N^{-1} \mathbf{A}' \mathbf{Q}^{-1} \mathbf{A} \Delta_N^{-1} \mathbf{D}_N' \end{aligned}$$

If the model includes an intercept, then $\hat{\alpha} = \bar{y}_{..} - \bar{x}_{..} \hat{\boldsymbol{\beta}}_f$, and the $\hat{v}_i$ are shifted to exclude $\hat{\alpha}$.

Variance and covariance estimates for $\hat{\alpha}$, $\hat{\mathbf{v}}$, and $\hat{\boldsymbol{\lambda}}$ are obtained by the delta method, because each of these quantities is a linear transformation of $\mathbf{y}^*$ and $\hat{\boldsymbol{\beta}}_f$.

One-Way Random-Effects Model (RANONE Option)

You perform one-way random-effects estimation by specifying the RANONE option in the MODEL statement. The specification for the one-way random-effects model is

$$u_{it} = v_i + e_{it}$$

where the v_i are iid with zero mean and variance σ_v^2 , and the e_{it} are iid with zero mean and variance σ_e^2 . Furthermore, a random-effects specification assumes that the error terms are mutually uncorrelated and that each error term is uncorrelated with $\mathbf{X}$.

Estimation proceeds in two steps. First, you obtain estimates of the variance components σ_v^2 and σ_e^2 . The CPANEL procedure provides five methods for estimating variance components; these methods are described in the following subsections.

Second, with the variance components in hand, you form a weight for each cross section,

$$\hat{\theta}_i = 1 - \hat{\sigma}_e / \hat{w}_i$$

where $\hat{w}_i^2 = T_i \hat{\sigma}_v^2 + \hat{\sigma}_e^2$. Taking $\hat{\theta}_i$, you form the partial deviations:

$$\tilde{y}_{it} = y_{it} - \hat{\theta}_i \bar{y}_i.$$

$$\tilde{\mathbf{x}}_{\alpha,it} = \mathbf{x}_{\alpha,it} - \hat{\theta}_i \bar{\mathbf{x}}_{\alpha,i}.$$

The random-effects estimation is then the result of OLS regression on the transformed data.

The CPANEL procedure provides five options for estimating variance components, as described in the following subsections.

Swamy-Arora Method

The Swamy and Arora (1972) method is the default method of estimating variance components; it can also be specified as the VCOMP=SA option in the MODEL statement. The Swamy-Arora method is part of a class of methods known as analysis of variance (ANOVA) estimators.

ANOVA estimators obtain variance components by solving a system of equations that is based on expected sums of squares. The following quadratic forms correspond to the within and between sums of squares, respectively:

$$q_e = \mathbf{u}' \mathbf{Q}_0 \mathbf{u}$$

$$q_v = \mathbf{u}' \mathbf{P}_0 \mathbf{u}$$

In these equations, $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$, $\mathbf{P}_0 = \text{diag}(\bar{\mathbf{J}}_{T_i})$, and $\mathbf{u}$ is the vector of true residuals.

The ANOVA methods differ only in how they estimate $\mathbf{u}$. The Swamy-Arora method substitutes into q_e the within residuals from one-way fixed-effects estimation and substitutes into q_v the residuals from between-groups regression.

The expected values of the quadratic forms are

$$E(\hat{\mathbf{u}}_w' \mathbf{Q}_0 \hat{\mathbf{u}}_w) = (M - N - K) \sigma_e^2$$

$$E(\hat{\mathbf{u}}_b' \mathbf{P}_0 \hat{\mathbf{u}}_b) = \left[M - \text{tr} \left\{ (\mathbf{X}'_{\alpha} \mathbf{P}_0 \mathbf{X}_{\alpha})^{-1} \mathbf{X}'_{\alpha} \mathbf{Z}_0 \mathbf{Z}'_0 \mathbf{X}_{\alpha} \right\} \right] \sigma_v^2 + (N - K - 1) \sigma_e^2$$

where $\mathbf{Z}_0 = \text{diag}(\mathbf{j}_{T_i})$.

Estimates of σ_v^2 and σ_e^2 are obtained by first setting the expected sums of squares to their observed values, and then solving.

Wallace-Hussain Method

You can use the Wallace and Hussain (1969) method of estimating variance components by specifying the VCOMP=WH option in the MODEL statement. The Wallace-Hussain method is an ANOVA method that uses the residuals from pooled (OLS) regression, $\hat{\mathbf{u}}_p$, in both quadratic forms.

The expected values of the quadratic forms are

$$E\left(\hat{\mathbf{u}}_p' \mathbf{Q}_0 \hat{\mathbf{u}}_p\right) = (d_1 - d_3)\sigma_v^2 + (M - N - K - 1 + d_2)\sigma_e^2$$

$$E\left(\hat{\mathbf{u}}_p' \mathbf{P}_0 \hat{\mathbf{u}}_p\right) = (M - 2d_1 + d_3)\sigma_v^2 + (N - d_2)\sigma_e^2$$

where

$$d_1 = \text{tr} \left\{ \left(\mathbf{X}'_\alpha \mathbf{X}_\alpha \right)^{-1} \mathbf{X}'_\alpha \mathbf{Z}_0 \mathbf{Z}'_0 \mathbf{X}_\alpha \right\}$$

$$d_2 = \text{tr} \left\{ \left(\mathbf{X}'_\alpha \mathbf{X}_\alpha \right)^{-1} \mathbf{X}'_\alpha \mathbf{P}_0 \mathbf{X}_\alpha \right\}$$

$$d_3 = \text{tr} \left\{ \left(\mathbf{X}'_\alpha \mathbf{X}_\alpha \right)^{-1} \mathbf{X}'_\alpha \mathbf{P}_0 \mathbf{X}_\alpha \left(\mathbf{X}'_\alpha \mathbf{X}_\alpha \right)^{-1} \mathbf{X}'_\alpha \mathbf{Z}_0 \mathbf{Z}'_0 \mathbf{X}_\alpha \right\}$$

Wansbeek-Kapteyn Method

You can use the Wansbeek-Kapteyn method of estimating variance components by specifying the VCOMP=WK option in the MODEL statement. The method is a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models. The method was also suggested by Amemiya (1971) for balanced data.

The Wansbeek and Kapteyn method is an ANOVA method that uses the within residuals from one-way fixed effects, $\hat{\mathbf{u}}_w$, in both quadratic forms.

The expected values of the quadratic forms are

$$E\left(\hat{\mathbf{u}}_w' \mathbf{Q}_0 \hat{\mathbf{u}}_w\right) = (M - N - K)\sigma_e^2$$

$$E\left(\hat{\mathbf{u}}_w' \mathbf{P}_0 \hat{\mathbf{u}}_w\right) = (N - 1 + d)\sigma_e^2 + \left(M - M^{-1} \sum_{i=1}^N T_i^2 \right) \sigma_v^2$$

where

$$d = \text{tr} \left\{ (\mathbf{X}' \mathbf{Q}_0 \mathbf{X})^{-1} \mathbf{X}' \mathbf{P}_0 \mathbf{X} \right\} - \text{tr} \left\{ (\mathbf{X}' \mathbf{Q}_0 \mathbf{X})^{-1} \mathbf{X}' \bar{\mathbf{J}}_M \mathbf{X} \right\}$$

Fuller-Battese Method

You can use the Fuller and Battese (1974) method of estimating variance components by specifying the VCOMP=FB option in the MODEL statement. Following Baltagi (2013, sec. 9.2), obtain $\hat{\sigma}_e^2$ as the mean square error (MSE) from one-way fixed effects. The cross-sectional variance is

$$\hat{\sigma}_v^2 = \frac{R(\mathbf{v}|\boldsymbol{\beta}) - (N-1)\hat{\sigma}_e^2}{M - \text{tr}\{\mathbf{Z}'_0\mathbf{X}_\alpha(\mathbf{X}'_\alpha\mathbf{X}_\alpha)^{-1}\mathbf{X}'_\alpha\mathbf{Z}_0\}}$$

where

$$R(\mathbf{v}|\boldsymbol{\beta}) = R(\boldsymbol{\beta}|\mathbf{v}) + R(\mathbf{v}) - R(\boldsymbol{\beta})$$

for

$$\begin{aligned} R(\mathbf{v}) &= \mathbf{y}'\mathbf{Z}_0(\mathbf{Z}'_0\mathbf{Z}_0)^{-1}\mathbf{Z}'_0\mathbf{y} \\ R(\boldsymbol{\beta}|\mathbf{v}) &= \mathbf{y}'_w\mathbf{X}'_w(\mathbf{X}'_w\mathbf{X}_w)^{-1}\mathbf{X}'_w\mathbf{y}_w \\ R(\boldsymbol{\beta}) &= \mathbf{y}'\mathbf{X}'_\alpha(\mathbf{X}'_\alpha\mathbf{X}_\alpha)^{-1}\mathbf{X}'_\alpha\mathbf{y} \end{aligned}$$

Nerlove Method

You can use the Nerlove (1971) method of estimating variance components by specifying the VCOMP=NL option in the MODEL statement. Nerlove's method provides a simple alternative to previous estimation strategies. You estimate σ_v^2 as the sample variance of the cross-sectional effects, estimated from a one-way fixed-effects regression. Specifically, $\hat{\sigma}_v^2 = (N-1)^{-1} \sum_{i=1}^N (\hat{v}_i - \bar{v})^2$, where $\bar{v}$ is the mean of the estimated fixed effects. You estimate σ_e^2 by taking the error sum of squares from one-way fixed-effects regression and then dividing by M .

Selecting the Appropriate Variance Component Method

Baltagi and Chang (1994) conducted an extensive simulation study regarding the finite-sample properties of the variance estimators that are supported by the CPANEL procedure. The choice of method has little bearing on estimates of regression coefficients, their standard errors, and estimation of the error variance σ_e^2 . If your goal is inference on $\boldsymbol{\beta}$, then the variance-component method will matter little.

The methods have varying performance in how they estimate σ_v^2 , the cross-sectional variance. All five methods tend to perform poorly if either the data are severely unbalanced or the ratio σ_v^2/σ_e^2 is much greater than 1.

The Nerlove method is the only method that guarantees a nonnegative estimate of σ_v^2 ; the other four methods reset a negative estimate to 0. However, the Nerlove method is particularly unsuitable for unbalanced data because the sample variance that it computes is not weighted by T_i .

Two-Way Random-Effects Model (RANTWO Option)

You perform two-way random-effects estimation by specifying the RANTWO option in the MODEL statement. The specification for the two-way random-effects model is

$$u_{it} = v_i + \lambda_t + e_{it}$$

where the v_i are iid with zero mean and variance σ_v^2 , the λ_t are iid with zero mean and variance σ_λ^2 , and the e_{it} are iid with zero mean and variance σ_e^2 . Furthermore, a random-effects specification assumes that the error terms are mutually uncorrelated and that each error term is uncorrelated with $\mathbf{X}$.

Estimation proceeds in two steps. First, you obtain estimates of the variance components σ_v^2 , σ_λ^2 , and σ_e^2 . The CPANEL procedure provides five methods for estimating variance components; these methods are described in the following subsections.

Second, with the variance-component estimates in hand, you transform the data in such a way that estimation can take place using ordinary least squares (OLS). In two-way models with unbalanced data, the transformation is quite complex. Throughout this section, $\mathbf{y}$ and $\mathbf{X}$ are treated as being sorted first by time, and then by cross-section within time. For the definitions of the design matrices $\mathbf{D}_N$ and $\mathbf{D}_T$, see the section “Two-Way Fixed-Effects Model (FIXTWO Option)” on page 496. The variance of $\mathbf{y}$ is

$$\mathbf{\Omega} = \sigma_e^2 \mathbf{I}_M + \sigma_v^2 \mathbf{D}_N \mathbf{D}_N' + \sigma_\lambda^2 \mathbf{D}_T \mathbf{D}_T'$$

and estimation proceeds as OLS regression of $\hat{\sigma}_e \hat{\mathbf{\Omega}}^{-1/2} \mathbf{y}$ on $\hat{\sigma}_e \hat{\mathbf{\Omega}}^{-1/2} \mathbf{X}_\alpha$.

Rather than invert the $M \times M$ matrix $\hat{\mathbf{\Omega}}$ directly, Wansbeek and Kapteyn (1989) provide the more convenient form

$$\hat{\sigma}_e^2 \hat{\mathbf{\Omega}}^{-1} = \mathbf{V} - \mathbf{V} \mathbf{D}_T \tilde{\mathbf{P}}^{-1} \mathbf{D}_T' \mathbf{V}$$

where

$$\begin{aligned} \mathbf{V} &= \mathbf{I}_M - \mathbf{D}_N \tilde{\Delta}_N^{-1} \mathbf{D}_N' \\ \tilde{\mathbf{P}} &= \tilde{\Delta}_T - \mathbf{D}_T' \mathbf{D}_N \tilde{\Delta}_N^{-1} \mathbf{D}_N' \mathbf{D}_T \end{aligned}$$

with $\tilde{\Delta}_N = \mathbf{D}_N' \mathbf{D}_N + (\hat{\sigma}_e^2 / \hat{\sigma}_v^2) \mathbf{I}_N$ and $\tilde{\Delta}_T = \mathbf{D}_T' \mathbf{D}_T + (\hat{\sigma}_e^2 / \hat{\sigma}_\lambda^2) \mathbf{I}_T$.

If the data are balanced, then the calculations are simplified considerably—the data are transformed from z_{it} to $z_{it} - \hat{\theta}_1 \bar{z}_{i.} - \hat{\theta}_2 \bar{z}_{.t} + \hat{\theta}_3 \bar{z}_{..}$, where

$$\begin{aligned} \hat{\theta}_1 &= 1 - \hat{\sigma}_e (T \hat{\sigma}_v^2 + \hat{\sigma}_e^2)^{-1/2} \\ \hat{\theta}_2 &= 1 - \hat{\sigma}_e (N \hat{\sigma}_\lambda^2 + \hat{\sigma}_e^2)^{-1/2} \\ \hat{\theta}_3 &= \hat{\theta}_1 + \hat{\theta}_2 + \hat{\sigma}_e (T \hat{\sigma}_v^2 + N \hat{\sigma}_\lambda^2 + \hat{\sigma}_e^2)^{-1/2} - 1 \end{aligned}$$

The CPANEL procedure provides five options for estimating variance components, as described in the following subsections.

Swamy-Arora Method

The Swamy and Arora (1972) method is the default method of estimating variance components; it can also be specified as the VCOMP=SA option in the MODEL statement. The Swamy-Arora method is part of a class of methods known as analysis of variance (ANOVA) estimators.

ANOVA estimators obtain variance components by solving a system of equations that is based on expected sums of squares. The following quadratic forms correspond to the two-way within sum of squares, the sum of squares between time periods, and the sum of squares between cross sections, respectively:

$$\begin{aligned} q_e &= \mathbf{u}' \mathbf{P} \mathbf{u} \\ q_\lambda &= \mathbf{u}' \mathbf{D}_T \Delta_T^{-1} \mathbf{D}_T' \mathbf{u} \\ q_v &= \mathbf{u}' \mathbf{D}_N \Delta_N^{-1} \mathbf{D}_N' \mathbf{u} \end{aligned}$$

The matrix $\mathbf{P}$ is the two-way within transformation defined in the section “Two-Way Fixed-Effects Model (FIXTWO Option)” on page 496, $\Delta_T = \mathbf{D}_T' \mathbf{D}_T$, $\Delta_N = \mathbf{D}_N' \mathbf{D}_N$, and $\mathbf{u}$ is the vector of true residuals.

The ANOVA methods differ only in how they estimate $\mathbf{u}$. The Swamy-Arora method substitutes into q_e the within residuals from two-way fixed-effects estimation, substitutes into q_λ the residuals from between-time-periods regression, and substitutes into q_v the residuals from between-cross-sections regression.

The expected values of the quadratic forms are

$$\begin{aligned} E(\hat{\mathbf{u}}_f' \mathbf{P} \hat{\mathbf{u}}_f) &= (M - N - T - K + 1)\sigma_e^2 \\ E(\hat{\mathbf{u}}_\lambda' \mathbf{P}_\lambda \hat{\mathbf{u}}_\lambda) &= \left[M - \text{tr} \left\{ (\mathbf{X}'_\alpha \mathbf{P}_\lambda \mathbf{X}_\alpha)^{-1} \mathbf{X}'_\alpha \mathbf{D}_T \mathbf{D}_T' \mathbf{X}_\alpha \right\} \right] \sigma_\lambda^2 + (T - K - 1)\sigma_e^2 \\ E(\hat{\mathbf{u}}_v' \mathbf{P}_v \hat{\mathbf{u}}_v) &= \left[M - \text{tr} \left\{ (\mathbf{X}'_\alpha \mathbf{P}_v \mathbf{X}_\alpha)^{-1} \mathbf{X}'_\alpha \mathbf{D}_N \mathbf{D}_N' \mathbf{X}_\alpha \right\} \right] \sigma_v^2 + (N - K - 1)\sigma_e^2 \end{aligned}$$

where $\mathbf{P}_\lambda = \mathbf{D}_T \Delta_T^{-1} \mathbf{D}_T'$ and $\mathbf{P}_v = \mathbf{D}_N \Delta_N^{-1} \mathbf{D}_N'$.

Estimates of σ_v^2 , σ_λ^2 , and σ_e^2 are obtained by setting the expected sums of squares to their observed values and solving.

Wallace-Hussain Method

You can use the Wallace and Hussain (1969) method of estimating variance components by specifying the VCOMP=WH option in the MODEL statement. The Wallace-Hussain method is an ANOVA method that uses the residuals from pooled (OLS) regression, $\hat{\mathbf{u}}_p$, in all three quadratic forms.

The expected values of the quadratic forms are

$$\begin{aligned} E(\hat{\mathbf{u}}_p' \mathbf{P} \hat{\mathbf{u}}_p) &= d_{11}\sigma_e^2 + d_{12}\sigma_v^2 + d_{13}\sigma_\lambda^2 \\ E(\hat{\mathbf{u}}_p' \mathbf{P}_\lambda \hat{\mathbf{u}}_p) &= d_{21}\sigma_e^2 + d_{22}\sigma_v^2 + d_{23}\sigma_\lambda^2 \\ E(\hat{\mathbf{u}}_p' \mathbf{P}_v \hat{\mathbf{u}}_p) &= d_{31}\sigma_e^2 + d_{32}\sigma_v^2 + d_{33}\sigma_\lambda^2 \end{aligned}$$

Define $\Sigma = (\mathbf{X}'_\alpha \mathbf{X}_\alpha)^{-1}$, which is the inverse crossproducts matrix from pooled regression. Also define $\mathbf{S}_v = \mathbf{X}'_\alpha \mathbf{D}_N \mathbf{D}_N' \mathbf{X}_\alpha$ and $\mathbf{S}_\lambda = \mathbf{X}'_\alpha \mathbf{D}_T \mathbf{D}_T' \mathbf{X}_\alpha$, which are the individual-level sum of squares and the time-

level sum of squares, respectively. The coefficients are

$$\begin{aligned}
 d_{11} &= M - N - T + 1 - \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P} \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) \\
 d_{12} &= \text{tr}(\mathbf{S}_v \boldsymbol{\Sigma} \mathbf{X}'_{\alpha} \mathbf{P} \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) \\
 d_{13} &= \text{tr}(\mathbf{S}_{\lambda} \boldsymbol{\Sigma} \mathbf{X}'_{\alpha} \mathbf{P} \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) \\
 d_{21} &= T - \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_{\lambda} \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) \\
 d_{22} &= T - 2\text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_{\lambda} \mathbf{D}_N \mathbf{D}'_N \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) + \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_{\lambda} \mathbf{X}_{\alpha} \boldsymbol{\Sigma} \mathbf{S}_v \boldsymbol{\Sigma}) \\
 d_{23} &= M - 2\text{tr}(\mathbf{S}_{\lambda} \boldsymbol{\Sigma}) + \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_{\lambda} \mathbf{X}_{\alpha} \boldsymbol{\Sigma} \mathbf{S}_{\lambda} \boldsymbol{\Sigma}) \\
 d_{31} &= N - \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_v \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) \\
 d_{32} &= M - 2\text{tr}(\mathbf{S}_v \boldsymbol{\Sigma}) + \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_v \mathbf{X}_{\alpha} \boldsymbol{\Sigma} \mathbf{S}_v \boldsymbol{\Sigma}) \\
 d_{33} &= N - 2\text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_v \mathbf{D}_T \mathbf{D}'_T \mathbf{X}_{\alpha} \boldsymbol{\Sigma}) + \text{tr}(\mathbf{X}'_{\alpha} \mathbf{P}_v \mathbf{X}_{\alpha} \boldsymbol{\Sigma} \mathbf{S}_{\lambda} \boldsymbol{\Sigma})
 \end{aligned}$$

Wansbeek-Kapteyn Method

You can use the Wansbeek-Kapteyn method of estimating variance components by specifying the VCOMP=WK option in the MODEL statement. The method is a specialization (Baltagi and Chang 1994) of the approach used by Wansbeek and Kapteyn (1989) for unbalanced two-way models.

The Wansbeek and Kapteyn method is an ANOVA method that uses the within residuals from two-way fixed effects, $\hat{\mathbf{u}}_f$, in all three quadratic forms.

The expected values of the quadratic forms are

$$\begin{aligned}
 E(\hat{\mathbf{u}}'_f \mathbf{P} \hat{\mathbf{u}}_f) &= (M - N - T - K + 1) \sigma_e^2 \\
 E(\hat{\mathbf{u}}'_f \mathbf{P}_{\lambda} \hat{\mathbf{u}}_f) &= (T + k_N - k_0) \sigma_e^2 + (T - \delta_N) \sigma_v^2 + (M - \delta_T) \sigma_{\lambda}^2 \\
 E(\hat{\mathbf{u}}'_f \mathbf{P}_v \hat{\mathbf{u}}_f) &= (N + k_T - k_0) \sigma_e^2 + (M - \delta_N) \sigma_v^2 + (N - \delta_T) \sigma_{\lambda}^2
 \end{aligned}$$

where $\delta_N = M^{-1} \sum_{i=1}^N T_i^2$ and $\delta_T = M^{-1} \sum_{t=1}^T N_t^2$. The other constants are defined by

$$\begin{aligned}
 k_0 &= 1 + M^{-1} \mathbf{j}'_M \mathbf{X} (\mathbf{X}' \mathbf{P} \mathbf{X})^{-1} \mathbf{X}' \mathbf{j}_M \\
 k_N &= \text{tr}\{(\mathbf{X}' \mathbf{P} \mathbf{X})^{-1} \mathbf{X}' \mathbf{P}_{\lambda} \mathbf{X}\} \\
 k_T &= \text{tr}\{(\mathbf{X}' \mathbf{P} \mathbf{X})^{-1} \mathbf{X}' \mathbf{P}_v \mathbf{X}\}
 \end{aligned}$$

When the NOINT option is specified, the variance-component equations change slightly: k_0 , δ_N , and δ_T are all replaced by 0.

Fuller-Battese Method

You can use the Fuller and Battese (1974) method of estimating variance components by specifying the VCOMP=FB option in the MODEL statement. Following the discussion in Baltagi, Song, and Jung (2002), the Fuller-Battese method is a variation of the three ANOVA methods discussed previously.

The quadratic form, q_e , is the same as in the previous methods, and $\mathbf{u}$ is estimated by the two-way within residuals $\hat{\mathbf{u}}_f$. The other two quadratic forms, q_λ and q_v , are replaced by the error sums of squares from one-way fixed-effects estimations.

The resulting system of equations is

$$\begin{aligned} E(\hat{\mathbf{u}}_f' \mathbf{P} \hat{\mathbf{u}}_f) &= (M - N - T - K + 1)\sigma_e^2 \\ E(\tilde{\mathbf{u}}_\lambda' \tilde{\mathbf{u}}_\lambda) &= (M - T - K)\sigma_e^2 + \left[M - T - \text{tr} \left\{ \mathbf{X}' \mathbf{W}_\lambda \mathbf{D}_N \mathbf{D}_N' \mathbf{W}_\lambda \mathbf{X} (\mathbf{X}' \mathbf{W}_\lambda \mathbf{X})^{-1} \right\} \right] \sigma_v^2 \\ E(\tilde{\mathbf{u}}_v' \tilde{\mathbf{u}}_v) &= (M - N - K)\sigma_e^2 + \left[M - N - \text{tr} \left\{ \mathbf{X}' \mathbf{W}_v \mathbf{D}_T \mathbf{D}_T' \mathbf{W}_v \mathbf{X} (\mathbf{X}' \mathbf{W}_v \mathbf{X})^{-1} \right\} \right] \sigma_\lambda^2 \end{aligned}$$

where $\mathbf{W}_\lambda = \mathbf{I}_M - \mathbf{P}_\lambda$, $\mathbf{W}_v = \mathbf{I}_M - \mathbf{P}_v$, $\tilde{\mathbf{u}}_\lambda$ are the residuals from a one-way model with time fixed effects, and $\tilde{\mathbf{u}}_v$ are the residuals from a one-way model with individual fixed effects.

Nerlove Method

You can use the Nerlove (1971) method of estimating variance components by specifying the VCOMP=NL option in the MODEL statement.

Begin by fitting a two-way fixed-effects model. The estimator of the error variance is

$$\hat{\sigma}_e^2 = M^{-1} \hat{\mathbf{u}}_f' \mathbf{P} \hat{\mathbf{u}}_f$$

You obtain $\hat{\sigma}_v^2$ as the sample variance of the N estimated individual effects, and $\hat{\sigma}_\lambda^2$ as the sample variance of the T estimated time effects.

Hausman-Taylor Estimation (HTAYLOR Option)

You perform Hausman-Taylor estimation by specifying the HTAYLOR option in the MODEL statement. The Hausman and Taylor (1981) model is a hybrid that combines the consistency of a fixed-effects model with the efficiency and applicability of a random-effects model. One-way random-effects models assume exogeneity of the regressors, namely that they are independent of both the cross-sectional and observation-level errors. When some regressors are correlated with the cross-sectional errors, the random effects model can be adjusted to deal with this form of endogeneity.

Consider the one-way model:

$$y_{it} = \mathbf{x}_{1it} \boldsymbol{\beta}_1 + \mathbf{x}_{2it} \boldsymbol{\beta}_2 + \mathbf{z}_{1i} \boldsymbol{\gamma}_1 + \mathbf{z}_{2i} \boldsymbol{\gamma}_2 + v_i + e_{it}$$

The regressors are subdivided so that $\mathbf{x}_{1it}$ and $\mathbf{x}_{2it}$ vary within cross sections whereas $\mathbf{z}_{1i}$ and $\mathbf{z}_{2i}$ do not and would otherwise be dropped from a fixed-effects model. The subscript 1 denotes variables that are independent of both error terms (exogenous variables), and the subscript 2 denotes variables that are

independent of the observation-level errors e_{it} but correlated with cross-sectional errors v_i . The intercept term (if your model has one) is included as part of $\mathbf{z}_{1i}$.

The Hausman-Taylor estimator is a two-stage least squares (2SLS) regression on data that are weighted similarly to data for random-effects estimation. The weights are functions of the estimated variance components.

The observation-level variance is estimated from a one-way fixed-effects model fit. Obtain $\mathbf{y}_w$, $\mathbf{X}_w$, and $\hat{\boldsymbol{\beta}}_w$ from the section “[One-Way Fixed-Effects Model \(FIXONE and FIXONETIME Options\)](#)” on page 494. Then $\hat{\sigma}_e^2 = \text{SSE}/(M - N)$, where

$$\text{SSE} = (\mathbf{y}_w - \mathbf{X}_w \hat{\boldsymbol{\beta}}_w)' (\mathbf{y}_w - \mathbf{X}_w \hat{\boldsymbol{\beta}}_w)$$

To estimate the cross-sectional error variance, form the mean-residual vector $\mathbf{r} = \mathbf{P}'_0(\mathbf{y} - \mathbf{X}_w \hat{\boldsymbol{\beta}}_w)$, where $\mathbf{P}_0 = \text{diag}(\bar{\mathbf{J}}_{T_i})$. You can use the mean residuals to obtain intermediate estimates of the coefficients for $\mathbf{z}_1$ and $\mathbf{z}_2$ via two-stage least squares (2SLS) estimation. At the first stage, use $\mathbf{x}_1$ and $\mathbf{z}_1$ as instrumental variables to predict $\mathbf{z}_2$. At the second stage, regress $\mathbf{r}$ on both $\mathbf{z}_1$ and the predicted $\mathbf{z}_2$ to obtain $\hat{\boldsymbol{\gamma}}_1^m$ and $\hat{\boldsymbol{\gamma}}_2^m$.

To estimate the cross-sectional variance, compute $\hat{\sigma}_v^2 = \{R(v)/N - \hat{\sigma}_e^2\}/\bar{T}$, where $\bar{T} = N/(\sum_{i=1}^N T_i^{-1})$ and

$$R(v) = (\mathbf{r} - \mathbf{Z}_1 \hat{\boldsymbol{\gamma}}_1^m - \mathbf{Z}_2 \hat{\boldsymbol{\gamma}}_2^m)' (\mathbf{r} - \mathbf{Z}_1 \hat{\boldsymbol{\gamma}}_1^m - \mathbf{Z}_2 \hat{\boldsymbol{\gamma}}_2^m)$$

The design matrices $\mathbf{Z}_1$ and $\mathbf{Z}_2$ are formed by stacking the data observations of $\mathbf{z}_{1i}$ and $\mathbf{z}_{2i}$, respectively.

After variance-component estimation, transform the dependent variable into partial deviations: $y_{it}^* = y_{it} - \hat{\theta}_i \bar{y}_{i.}$. Likewise, transform the regressors to form $\mathbf{x}_{1it}^*$, $\mathbf{x}_{2it}^*$, $\mathbf{z}_{1i}^*$, and $\mathbf{z}_{2i}^*$. The partial weights $\hat{\theta}_i$ are determined by $\hat{\theta}_i = 1 - \hat{\sigma}_e/\hat{w}_i$, with $\hat{w}_i^2 = T_i \hat{\sigma}_v^2 + \hat{\sigma}_e^2$.

Finally, you obtain the Hausman-Taylor estimates by performing 2SLS regression of y_{it}^* on $\mathbf{x}_{1it}^*$, $\mathbf{x}_{2it}^*$, $\mathbf{z}_{1i}^*$, and $\mathbf{z}_{2i}^*$. For the first-stage regression, use the following instruments:

- $\bar{x}_{it}$, the deviations from cross-sectional means for all time-varying variables (correlated and uncorrelated) for the i th cross section during time period t
- $(1 - \hat{\theta}_i) \bar{x}_{1i.}$, where $\bar{x}_{1i.}$ are the means of the time-varying exogenous variables for the i th cross section
- $(1 - \hat{\theta}_i) \mathbf{z}_{1i}$

Multiplication by the factor $(1 - \hat{\theta}_i)$ is redundant in balanced data, but necessary in the unbalanced case to produce accurate instrumentation; see Gardner (1998).

Let k_1 equal the number of regressors in $\mathbf{x}_1$, and let g_2 equal the number of regressors in $\mathbf{z}_2$. Then the Hausman-Taylor model is identified only if $k_1 \geq g_2$; otherwise, no estimation takes place.

Hausman and Taylor (1981) describe a specification test that compares their model to fixed effects. For a null hypothesis of fixed effects, Hausman's m statistic is calculated by comparing the parameter estimates and variance matrices for both models identically to how it is calculated for one-way random effects models; for more information, see the section “[Hausman Specification Tests](#)” on page 521. However, the degrees of freedom of the test are not based on matrix rank but instead are equal to $k_1 - g_2$.

Amemiya-MaCurdy Estimation (AMACURDY Option)

You perform Amemiya-MaCurdy estimation by specifying the AMACURDY option in the MODEL statement. The Amemiya and MaCurdy (1986) model is similar to the Hausman-Taylor model. Following the development in the section “Hausman-Taylor Estimation (HTAYLOR Option)” on page 503, estimation is identical up to the final 2SLS instrumental variables regression. In addition to the set of instruments used by the Hausman-Taylor estimator, use the following:

- $\mathbf{x}_{1i1}, \mathbf{x}_{1i2}, \dots, \mathbf{x}_{1iT}$

For each observation in the i th cross section, you use the data on the time-varying exogenous regressors for the entire cross section. Because of the structure of the added instruments, the Amemiya-MaCurdy estimator can be applied only to balanced data.

The Amemiya-MaCurdy model attempts to gain efficiency over Hausman-Taylor by adding instruments. This comes at a price of a more stringent assumption on the exogeneity of the $\mathbf{x}_1$ variables. Although the Hausman-Taylor model requires only that the cross-sectional means of $\mathbf{x}_1$ be orthogonal to v_i , the Amemiya-MaCurdy estimation requires orthogonality at every point in time; see Baltagi (2013, sec. 7.4).

A Hausman specification test is provided to test the validity of the added assumption. Define $\alpha' = (\beta_1', \beta_2', \gamma_1', \gamma_2')$, its Hausman-Taylor estimate as $\hat{\alpha}_{HT}$, and its Amemiya-MaCurdy estimate as $\hat{\alpha}_{AM}$. Under the null hypothesis, both estimators are consistent and $\hat{\alpha}_{AM}$ is efficient. The Hausman test statistic is

$$m = (\hat{\alpha}_{HT} - \hat{\alpha}_{AM})' (\hat{\Sigma}_{HT} - \hat{\Sigma}_{AM})^{-1} (\hat{\alpha}_{HT} - \hat{\alpha}_{AM})$$

where $\hat{\Sigma}_{HT}$ and $\hat{\Sigma}_{AM}$ are variance-covariance estimates of $\hat{\alpha}_{HT}$ and $\hat{\alpha}_{AM}$, respectively. Under the null hypothesis, m follows a χ^2 distributed with degrees of freedom equal to the rank of $(\hat{\Sigma}_{HT} - \hat{\Sigma}_{AM})^{-1}$.

Instrumental Variables Regression

Recall the original specification of the regression model:

$$y_{it} = \alpha + \sum_{k=1}^K x_{itk} \beta_k + u_{it} \quad i = 1, \dots, N; t = 1, \dots, T_i$$

Consider that a subset of the regressors are *endogenous*—that is, these regressors are correlated with the observation-level errors u_{it} .

Formally, divide $\mathbf{x}$ and $\boldsymbol{\beta}$ so that

$$y_{it} = \mathbf{x}_{1it} \boldsymbol{\beta}_1 + \mathbf{x}_{2it} \boldsymbol{\beta}_2 + u_{it}$$

where $\mathbf{x}_{1it}$ are k_1 uncorrelated (exogenous) regressors, $\mathbf{x}_{2it}$ are k_2 endogenous regressors, and the intercept (if your model has one) is contained in $\mathbf{x}_{1it}$.

In matrix notation, the model is

$$\mathbf{y} = \mathbf{X}_1 \boldsymbol{\beta}_1 + \mathbf{X}_2 \boldsymbol{\beta}_2 + \mathbf{u}$$

where the matrix rows are arranged by cross section, and by time within cross section.

Instrumental variables (IV) regression is the process of using external regressors, called *instruments*, to deal with the endogeneity. Let $\mathbf{Z}$ represent a set of p instruments such that $p \geq k_2$. The set of endogenous regressors, $\mathbf{X}_2$, are specified as effects in the ENDOGENOUS statement. The set of external instruments, $\mathbf{Z}$, are specified as effects in the INSTRUMENTS statement. Define $\mathbf{X} = [\mathbf{X}_1 \mathbf{X}_2]$.

The CPANEL procedure performs instrumental variables regression by the method of two-stage least squares (2SLS) or the efficient GMM. Two-stage least squares is a special case of the GMM and is equivalent to the one-step GMM method. The efficient GMM method, which is also called two-step GMM, is a GMM that uses the optimal weighting matrix. The optimal weighting matrix is based on the residuals from the one-step GMM. If you define the estimated residual vector as $\hat{\mathbf{u}}$ and the degrees of freedom as df , then you can obtain the estimated variance of the error term as $\sigma_u^2 = \mathbf{u}'\mathbf{u}/df$ and use it to form the optimal weighting matrix.

The 2SLS estimator can be obtained as

$$\hat{\boldsymbol{\beta}}_{2SLS} = [\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}]^{-1}\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{y}$$

The estimated variance-covariance matrix of the 2SLS estimator is

$$\text{Var}(\hat{\boldsymbol{\beta}}_{2SLS}) = \hat{\sigma}^2[\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}]^{-1}$$

You can also obtain the heteroscedasticity robust standard error for 2SLS by specifying the ROBUST option. Define $\hat{\Omega}$ as the diagonal matrix of squared residuals from the 2SLS estimation:

$$\hat{\Omega} = \begin{pmatrix} \hat{u}_1^2 & & 0 \\ & \ddots & \\ 0 & & \hat{u}_{NT}^2 \end{pmatrix}$$

Define $\mathbf{P}_Z = \mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'$ and $\mathbf{W}_2 = \mathbf{Z}'\hat{\Omega}\mathbf{Z}$. Then the estimated robust variance-covariance matrix of the 2SLS estimator is

$$\text{Var}_r(\hat{\boldsymbol{\beta}}_{2SLS}) = [\mathbf{X}'\mathbf{P}_Z\mathbf{X}]^{-1}[\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{W}_2(\mathbf{Z}'\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}][\mathbf{X}'\mathbf{P}_Z\mathbf{X}]^{-1}$$

The two-step GMM estimator can be obtained as

$$\hat{\boldsymbol{\beta}}_{GMM} = [\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\hat{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}]^{-1}\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\hat{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{y}$$

with asymptotic variance

$$\text{Var}(\hat{\boldsymbol{\beta}}_{GMM}) = [\mathbf{X}'\mathbf{Z}(\mathbf{Z}'\hat{\Omega}\mathbf{Z})^{-1}\mathbf{Z}'\mathbf{X}]^{-1}$$

You can also obtain the heteroscedasticity robust standard error for two-step GMM. Define $\hat{\Omega}_2$ as the diagonal matrix of squared residuals from the two-step GMM estimation and $\mathbf{W}_3 = \mathbf{Z}'\hat{\Omega}_2\mathbf{Z}$. Then the estimated robust variance-covariance matrix of the two-step GMM estimator is

$$\text{Var}_r(\hat{\boldsymbol{\beta}}_{GMM}) = [\mathbf{X}'\mathbf{Z}(\mathbf{W}_2)^{-1}\mathbf{Z}'\mathbf{X}]^{-1}[\mathbf{X}'\mathbf{Z}(\mathbf{W}_2)^{-1}\mathbf{W}_3(\mathbf{W}_2)^{-1}\mathbf{Z}'\mathbf{X}][\mathbf{X}'\mathbf{Z}(\mathbf{W}_2)^{-1}\mathbf{Z}'\mathbf{X}]^{-1}$$

Similar to the two-step GMM estimation for a dynamic panel in the section “[Estimation](#)” on page 514, you can obtain a bias-corrected variance of $\hat{\boldsymbol{\beta}}_{GMM}$ for IV models by using the BIASCORRECTED option. The

formulas are as the same as those from the section “[Estimation](#)” on page 514. Define the one-step and two-step residuals as $\hat{u}_{1i} = y_i - \mathbf{X}_i \hat{\beta}_{2SLS}$ and $\hat{u}_{2i} = y_i - \mathbf{X}_i \hat{\beta}_{GMM}$, respectively. Also define

$$\mathbf{P}_e = \sum_{i=1}^N \mathbf{Z}_i' \hat{u}_{2i}; \quad \mathbf{P}_x = \sum_{i=1}^N \mathbf{Z}_i' \mathbf{X}_i^s$$

Formulate the matrix $\mathbf{D}$ such that its k th column is $\mathbf{D}_k = \mathbf{V}_2 \mathbf{P}_x' (W_2)^{-1} \mathbf{F}_k (W_2)^{-1} \mathbf{P}_e$, where $\mathbf{V}_2 = \text{Var}(\hat{\beta}_{GMM})$. The matrix $\mathbf{F}_k$ is the quadratic form

$$\mathbf{F}_k = \sum_{i=1}^{NT} \mathbf{Z}_i' \left(\mathbf{x}_{ik} \hat{u}_{1i} + \hat{u}_{1i} \mathbf{x}_{ik}' \right) \mathbf{Z}_i$$

where $\mathbf{x}_{ik}$ is the k th column of $\mathbf{X}_i$. Note that the $\mathbf{F}_k$ here is different from the $\mathbf{F}_k$ in the dynamic panel section. By using this $\mathbf{F}_k$, the bias-corrected standard errors only correct for the bias from the two-step GMM, but not robust to serial correlation.

The Windmeijer (2005) bias-corrected variance is

$$\text{Var}^w(\hat{\beta}_{GMM}) = \mathbf{V}_2 + \mathbf{D} \mathbf{V}_2 + \mathbf{V}_2 \mathbf{D}' + \mathbf{D} \mathbf{V}_1^r \mathbf{D}'$$

where $\mathbf{V}_1^r$ is the robust variance estimate of $\hat{\beta}_{2SLS}$.

Depending on the error structure of u_{it} , there are eight IV models available, as described in the following subsections. In each model different $\mathbf{X}$, $\mathbf{Z}$, and $\mathbf{y}$ are substituted in the preceding formulas to obtain the 2SLS and the GMM estimators.

Instrumental Variables Pooled Regression (IVPOOLED Option)

You perform IV pooled regression by specifying the IVPOOLED option in the MODEL statement. Pooled model uses the standard regression model without any cross-sectional or time effects. The error structure is simply $u_{it} = e_{it}$, where the e_{it} are iid with zero mean and variance σ_e^2 . The errors e_{it} are uncorrelated with $\mathbf{x}_{1it}$, but correlated with $\mathbf{x}_{2it}$. The degree of freedom is $M - K - 1$.

Instrumental Variables Between-Groups Regression (IVBTWNG Option)

You perform IV between-groups regression by specifying the IVBTWNG option in the MODEL statement. When the data are balanced, between-groups IV model estimation is two-stage least squares (2SLS) regression or two-step GMM estimation performed on data that have been collapsed into cross-sectional means. When the data are unbalanced, the regression is weighted to assign more importance to larger cross sections. The cross-sectional means are multiplied by the weighting factor $w_i = \sqrt{T_i / \bar{T}}$, where $\bar{T} = M/N$ is the average cross section size.

Instrumental Variables One-Way Fixed Effects (IVFIXONE Option)

You perform IV one-way fixed-effects estimation by specifying the IVFIXONE option in the MODEL statement. The error structure for the one-way fixed-effects model is

$$u_{it} = v_i + e_{it}$$

where the v_i are nonrandom parameters that are restricted to sum to 0, and the e_{it} are iid with zero mean and variance σ_e^2 . The errors e_{it} are uncorrelated with $\mathbf{x}_{1it}$, but correlated with $\mathbf{x}_{2it}$.

The IV fixed-effects model can be estimated as an IV pooled regression, treating the v_i as coefficients on dummy variables that identify the cross sections. However, when N is large, you might want to estimate only β and not v_i .

Let $\mathbf{Q}_0 = \text{diag}(\mathbf{E}_{T_i})$. The matrix $\mathbf{Q}_0$ is the within transformation that removes means (and v_i) from the estimation. Define $\mathbf{y}_w = \mathbf{Q}_0\mathbf{y}$, and use the same transformation to form $\mathbf{X}_{1w}$, $\mathbf{X}_{2w}$ and $\mathbf{Z}_w$. Because the within transformation also removes the intercept term, the intercept is not included as part of $\mathbf{X}_1$.

The within-group estimates $\hat{\beta}_{\text{WIV}}$, $\text{Var}(\hat{\beta}_{\text{WIV}})$ can be obtained by substituting $\mathbf{y}_w$, $\mathbf{X}_w$, and $\mathbf{Z}_w$ into the general estimation equation in section “[Instrumental Variables Regression](#)” on page 505. You can obtain these estimates by using 2SLS method or two-step GMM method. When forming the error variance $\hat{\sigma}_e^2$, the error degrees of freedom are adjusted to equal $M - N - K$ to account for the N fixed effects.

The estimate of the intercept of the IVFIXONE model is

$$\hat{\alpha} = \bar{y}_{..} - \bar{x}_{..}\hat{\beta}_{\text{WIV}}$$

where $\bar{y}_{..}$ is the overall mean of y_{it} and $\bar{x}_{..}$ is the overall mean of x_{it} .

Fixed effects are not estimated as part of the regression but can be obtained by specifying the PRINTFIXED option in the MODEL statement. Each fixed effect in 2SLS is estimated as

$$\hat{v}_i = \bar{y}_{i.} - \bar{x}_{i.}\hat{\beta}_{\text{WIV}}$$

where $\bar{y}_{i.}$ and $\bar{x}_{i.}$ are cross-sectional means.

Variance estimates of $\hat{\alpha}$ and $\hat{v}_i$ are obtained by the delta method. If you specify the NOINT option, then the $\hat{v}_i$ are shifted to absorb $\hat{\alpha}$.

When the estimation method is 2SLS, PROC CPANEL reports a poolability test F . The F test assumes the null hypothesis that all fixed effects are jointly 0. Following the methodology of Wooldridge (2002, pp. 98–99) for restricted 2SLS, the test statistic is

$$F = \frac{(\text{SSE}_{2r} - \text{SSE}_{2u}) / (N - 1)}{\text{SSE}_u / (M - N - K)} \sim F(N - 1, M - N - K)$$

SSE_u is the final unrestricted error sum of squares

$$\text{SSE}_u = \left(\mathbf{y}_w - \mathbf{X}_{1w}\hat{\beta}_{1,\text{WIV}} - \mathbf{X}_{2w}\hat{\beta}_{2,\text{WIV}} \right)' \left(\mathbf{y}_w - \mathbf{X}_{1w}\hat{\beta}_{1,\text{WIV}} - \mathbf{X}_{2w}\hat{\beta}_{2,\text{WIV}} \right)$$

SSE_{2u} is the second-stage unrestricted error sum of squares

$$\text{SSE}_{2u} = \left(\mathbf{y}_w - \mathbf{X}_{1w}\hat{\beta}_{1,\text{WIV}} - \hat{\mathbf{X}}_{2w}\hat{\beta}_{2,\text{WIV}} \right)' \left(\mathbf{y}_w - \mathbf{X}_{1w}\hat{\beta}_{1,\text{WIV}} - \hat{\mathbf{X}}_{2w}\hat{\beta}_{2,\text{WIV}} \right)$$

and SSE_{2r} is the second-stage restricted error sum of squares, which is equal to the residual sum of squares from a pooled OLS regression of $\mathbf{y}$ on $\mathbf{X}_1$ and $\mathbf{X}_2^* = \hat{\mathbf{X}}_{2w} + \mathbf{P}_0\mathbf{X}_2$.

Instrumental Variables One-Way Time Fixed Effects (IVFIXONETIME Option)

You perform IV one-way time fixed-effects estimation by specifying the IVFIXONETIME option in the MODEL statement. The error structure for the one-way time fixed-effects model is

$$u_{it} = \lambda_t + e_{it}$$

where the λ_t are nonrandom parameters that are restricted to sum to 0, and the e_{it} are iid with zero mean and variance σ_e^2 . The errors e_{it} are uncorrelated with $\mathbf{x}_{1it}$, but correlated with $\mathbf{x}_{2it}$.

The steps of the estimation process of the one-way time fixed-effects model are the same as they are for the one-way fixed-effects model in the section “[Instrumental Variables One-Way Fixed Effects \(IVFIXONE Option\)](#)” on page 507, except IVFIXONETIME uses a different within-group transformation matrix $\mathbf{Q}_0 = \mathbf{I}_M - \bar{\mathbf{J}}_p \otimes \mathbf{I}_T$. By using $\mathbf{Q}_0$, the within-group transformation removes the time mean rather than the cross section means.

Instrumental Variables One-Way Time Fixed Effects (IVFIXTWO Option)

You perform IV two-way fixed-effects estimation by specifying the IVFIXTWO option in the MODEL statement. The error specification for the two-way fixed-effects model is

$$u_{it} = v_i + \lambda_t + e_{it}$$

where the v_i and λ_t are nonrandom parameters to be estimated. Assume the identifiability restriction $\sum_t \lambda_t = 0$.

To estimate the IV two-way fixed-effects model, first, a within transformation is needed to remove the cross-section means and time means. This step is the same as it is in section “[Two-Way Fixed-Effects Model \(FIXTWO Option\)](#)” on page 496 for both balanced and unbalanced panel. After the transformation is done, the within-group estimates $\hat{\beta}_{WIV}$, $\text{Var}(\hat{\beta}_{WIV})$ can be obtained by substituting $\mathbf{y}_w$, $\mathbf{X}_w$, and $\mathbf{Z}_w$ into the general estimation equation in section “[Instrumental Variables Regression](#)” on page 505.

Instrumental Variables One-Way Random Effects (IVRANONE Option)

You perform IV one-way random-effects estimation by specifying the IVRANONE option in the MODEL statement. The specification for the one-way random-effects model is

$$u_{it} = v_i + e_{it}$$

where the v_i are iid with zero mean and variance σ_v^2 , and the e_{it} are iid with zero mean and variance σ_e^2 . The regressors in $\mathbf{x}_{1it}$ are orthogonal to e_{it} , but the regressors in $\mathbf{x}_{2it}$ are correlated with e_{it} . This form of endogeneity is different from that assumed by Hausman and Taylor (1981), where $\mathbf{x}_{2it}$ is correlated with v_i but not with e_{it} .

The estimation performed by the CPANEL procedure is based on the error-component two-stage least squares (EC2SLS) method of Baltagi (1981). Estimation proceeds in two steps.

First, estimates of the variance components are obtained by using a variant of the Swamy-Arora method. Consider the system of equations

$$\begin{aligned} E(\hat{\mathbf{u}}_F' \mathbf{Q}_0 \hat{\mathbf{u}}_F) &= (M - N - K)\sigma_e^2 \\ E(\hat{\mathbf{u}}_B' \mathbf{P}_0 \hat{\mathbf{u}}_B) &= \left[M - \text{tr} \left\{ (\mathbf{X}'_\alpha \mathbf{P}_0 \mathbf{X}_\alpha)^{-1} \mathbf{X}'_\alpha \mathbf{Z}_0 \mathbf{Z}'_0 \mathbf{X}_\alpha \right\} \right] \sigma_v^2 + (N - K - 1)\sigma_e^2 \end{aligned}$$

where $\hat{u}_F$ are the residuals from IV one-way fixed effects, $\hat{u}_B$ are the residuals from IV between-groups regression, and the other quantities are as defined in the section “[Swamy-Arora Method](#)” on page 497. Estimates of σ_v^2 and σ_e^2 are obtained by setting the expected sums of squares to their observed values and solving.

Second, with the variance components in hand, you form a weight for each cross section:

$$\hat{\theta}_i = 1 - \hat{\sigma}_e / \hat{w}_i$$

where $\hat{w}_i^2 = T_i \hat{\sigma}_v^2 + \hat{\sigma}_e^2$. Taking $\hat{\theta}_i$, you form the partial deviations $y_{it}^* = y_{it} - \hat{\theta}_i \bar{y}_{i.}$, and similarly to form x_{1it}^* , x_{2it}^* , and z_{it}^* . Estimation then proceeds as a 2SLS or two-step GMM estimation of y_{it}^* on x_{1it}^* and x_{2it}^* . The following instruments are used in the estimation: x_{1it}^* , $\bar{x}_{1i.}$, z_{it}^* , and $\bar{z}_{i.}$. When the GMM=TWOSTEP option is specified, the estimation of the variance by the Swamy-Arora method is based on 2SLS estimation of within-group estimation and between-group estimation.

A Hausman specification test that compares IV random effects to IV fixed effects is formed by using the method described in the section “[Hausman Specification Tests](#)” on page 521. Failure to reject the null hypothesis favors the random-effects specification.

Instrumental Variables Generalized Two-Stage Least Squares (IVG2SLS Option)

You perform IV generalized two-stage least squares estimation by specifying the IVG2SLS option in the MODEL statement. The model specification and the model estimation steps are as the same as they are for the IVRANONE option in the section “[Instrumental Variables One-Way Random Effects \(IVRANONE Option\)](#)” on page 509, except for the choice of instrumental variables.

According to Baltagi (1981), in the generalized two-stage least squares model, the following instruments are used in the estimation: x_{1it}^* and z_{it}^* . The instrument z_{it}^* always includes an intercept whether an intercept is specified or not. Asymptotically, the estimates from the IVG2SLS and IVRANONE options yield the same variance-covariance matrix. In a small sample, the IVRANONE option can be more efficient by including the redundant instruments $\bar{x}_{1i.}$ and $\bar{z}_{i.}$.

Instrumental Variables Two-Way Random Effects (IVRANTWO Option)

You perform IV two-way random-effects estimation by specifying the IVRANTWO option in the MODEL statement. The specification for the error term of the IV two-way random-effects model is

$$u_{it} = v_i + \lambda_t + e_{it}$$

where the v_i are iid with zero mean and variance σ_v^2 , the λ_t are iid with zero mean and variance σ_λ^2 , and the e_{it} are iid with zero mean and variance σ_e^2 . Furthermore, a random-effects specification assumes that the error terms are mutually uncorrelated and that each error term is uncorrelated with $\mathbf{X}$.

IVRANTWO deals only with balanced panel data. The estimation proceeds in three steps, and the details are the same as they are for the RANTWO model in Baltagi (2013, sec. 3.3). First, estimate the variance components σ_v^2 , σ_λ^2 , and σ_e^2 . Define $Q_1 = I_N \otimes I_T$, $Q_2 = I_N \otimes \bar{J}_T$, $Q_3 = \bar{J}_N \otimes I_T$, $Q_4 = \bar{J}_N \otimes \bar{J}_T$, and $Q = Q_1 - Q_2 - Q_3 + k_0 Q_4$. If an intercept is specified, $k_0 = 1$; if an intercept is not specified, $k_0 = 0$. Run 2SLS regression on Qy , QX , and QZ to obtain the sum of squared errors for IVFIXTWO and name it sse_1 . Also define the degrees of freedom for IVFIXTWO to be df_1 . Run 2SLS regression on Q_2y , Q_2X , and Q_2Z to obtain the sum of squared errors for IVBTWNG and name it sse_2 . Also define the degrees of freedom for IVBTWNG to be df_2 . Run 2SLS regression on Q_3y , Q_3X , and Q_3Z to obtain the

sum of squared errors for IV between times and name it sse_3 . Also define the degrees of freedom for IV between times to be df_3 . Define

$$\hat{\lambda}_1 = \hat{\sigma}_e^2 = sse_1/df_1$$

$$\hat{\lambda}_2 = sse_2/df_2$$

$$\hat{\lambda}_3 = sse_3/df_3$$

The estimated variances are

$$\hat{\sigma}_v^2 = (\hat{\lambda}_2 - \hat{\lambda}_1)/T$$

$$\hat{\sigma}_\lambda^2 = (\hat{\lambda}_3 - \hat{\lambda}_1)/N$$

Define $\lambda_4 = T\sigma_v^2 + N\sigma_\lambda^2 + \sigma_e^2$, and obtain

$$\theta_1 = 1 - \sigma_e/\lambda_2^{1/2}$$

$$\theta_2 = 1 - \sigma_e/\lambda_3^{1/2}$$

$$\theta_3 = \theta_1 + \theta_2 + (\sigma_e/\lambda_4^{1/2}) - 1$$

Second, transform the data using θ_1 , θ_2 , and θ_3 . Define $Q_r = Q_1 - \theta_1 Q_2 - \theta_2 Q_3 + \theta_3 Q_4$. The transformed variables are obtained as $Q_r y$, $Q_r X$, and $Q_r Z$. Lastly, substitute the transformed variables into the general estimation equation that is shown in the section “[Instrumental Variables Regression](#)” on page 505 to obtain the estimates for the IVRANTWO model. Notice that if $\sigma_e^2 = 0$, this model collapses to the IVPOOLED model. If $\sigma_\lambda^2 = 0$ and $\sigma_v^2 = 0$, this model also collapses to the IVPOOLED model. If $\sigma_\lambda^2 = 0$ and $\sigma_v^2 > 0$, this model collapses to the IVRANONE model. If $\sigma_\lambda^2 > 0$ and $\sigma_v^2 = 0$, this model collapses to the IVRANONE model with respect to time.

Similar to the IVRANONE model, when the estimation option is two-step GMM, the variance components are obtained using 2SLS. When $\sigma_\lambda^2 > 0$, $\sigma_v^2 > 0$, and $\sigma_e^2 > 0$, the instrumental variables include only the transformed exogenous variable $\mathbf{X}_1^*$ and the transformed instrumental variable $\mathbf{Z}^*$ without the redundant instruments such as cross-section means and time means.

Dynamic Panel Estimation (DYNDIFF and DYNSSYS Options)

You perform dynamic panel estimation that uses first differences by specifying the DYNDIFF option in the MODEL statement. For dynamic panel estimation that uses a full system of difference and level equations, specify the DYNSSYS option. For an example of dynamic panel estimation, see [Example 11.5](#).

Dynamic panel models are regression models that include lagged versions of the dependent variable as covariates. Consider the following panel regression, which includes L lags of the dependent variable:

$$y_{it} = \sum_{j=1}^L \phi_j y_{i, t-j} + \sum_{k=1}^K x_{itk} \beta_k + v_i + \epsilon_{it}$$

The effect v_i is common to all observations for that individual, so it is correlated with any lagged y because it played a role in its realization. For this reason, lagged dependent variables are endogenous regressors and require special consideration.

First Differencing

For ease of notation, consider the special case $L = K = 1$. A first attempt to remove the source of the correlation would be to take first differences, which removes v_i . That is,

$$\Delta y_{it} = \phi \Delta y_{i,t-1} + \Delta x_{it} \beta + \eta_{it}$$

where $\Delta y_{it} = y_{i,t} - y_{i,t-1}$, $\Delta x_{it} = x_{i,t} - x_{i,t-1}$, and $\eta_{it} = \epsilon_{i,t} - \epsilon_{i,t-1}$. Even though the individual effects are removed, the problem of endogeneity persists because $\Delta y_{i,t-1}$ is correlated with the differenced error term η_{it} . That is because $\epsilon_{i,t-1}$ is a component of $y_{i,t-1}$ (Nickell 1981).

Arellano and Bond (1991) show that you can use the generalized method of moments (GMM) to obtain a consistent estimator. In GMM parlance, the moment condition that $E\{(\Delta y_{i,t-1})\eta_{it}\} = 0$ is violated. Estimation requires a set of instrumental variables that do meet their moment conditions and that can adequately predict $\Delta y_{i,t-1}$. A natural set of instruments is $y_{i,t-2}$ and all other previous realizations of y . These lags of y are not correlated with $\epsilon_{i,t-1}$ because they occurred before time $t - 1$. Given the autoregressive nature of the model, $y_{i,t-1}$ (and hence $\Delta y_{i,t-1}$) is well predicted by its previous values.

Begin with $t = 3$, the first time period in which the differenced model holds. The dynamic regression model for individual i can be expressed as

$$\mathbf{y}_i^d = \mathbf{X}_i^d \boldsymbol{\gamma} + \boldsymbol{\eta}_i^d$$

where

$$\mathbf{y}_i^d = \begin{pmatrix} \Delta y_{i3} \\ \Delta y_{i4} \\ \vdots \\ \Delta y_{iT} \end{pmatrix} \quad \mathbf{X}_i^d = \begin{pmatrix} \Delta y_{i2} & \Delta x_{i3} \\ \Delta y_{i3} & \Delta x_{i4} \\ \vdots & \vdots \\ \Delta y_{i,T-1} & \Delta x_{iT} \end{pmatrix} \quad \boldsymbol{\gamma} = \begin{pmatrix} \phi \\ \beta \end{pmatrix} \quad \boldsymbol{\eta}_i^d = \begin{pmatrix} \eta_{i3} \\ \eta_{i4} \\ \vdots \\ \eta_{iT} \end{pmatrix}$$

Proceeding with the idea that you can use $(y_{i1}, \dots, y_{i,t-2})$ as instruments for the endogenous covariate $\Delta y_{i,t-1}$ for $t = 3, \dots, T$, the instrument matrix for the lagged dependent variables is

$$\mathbf{Z}_i^d = \begin{pmatrix} y_{i1} & 0 & 0 & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & y_{i1} & y_{i2} & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 0 & y_{i1} & y_{i2} & y_{i3} & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & y_{i1} & \cdots & y_{i,T-2} \end{pmatrix}$$

This extends naturally to $L > 1$ and $K > 1$; simply add columns to $\mathbf{X}_i^d$ and elements to $\boldsymbol{\gamma}$ as appropriate. When an observation is either missing or lost because of missing lags, delete the corresponding rows of $\mathbf{y}_i^d$, $\mathbf{X}_i^d$, $\boldsymbol{\eta}_i^d$, and $\mathbf{Z}_i^d$. Even if an observation is not missing with respect to the regression model, some of the lagged instruments might not be available because previous observations are missing. When that occurs, replace any missing instrument with 0.

When you specify the DYNDIFF option in the MODEL statement, PROC CPANEL by default treats x variables as exogenous and uses a projection that leaves these variables unchanged in the differenced regression. The full instrument matrix is then $\mathbf{Z}_i = (\mathbf{Z}_i^d, \mathbf{D}_i)$, where

$$\mathbf{D}_i = \begin{pmatrix} \Delta x_{i31} & \Delta x_{i32} & \cdots & \Delta x_{i3K} \\ \Delta x_{i41} & \Delta x_{i42} & \cdots & \Delta x_{i4K} \\ \vdots & \vdots & \vdots & \vdots \\ \Delta x_{iT1} & \Delta x_{iT2} & \cdots & \Delta x_{iT K} \end{pmatrix}$$

When $L = 1$, the default $\mathbf{Z}_i$ has $(T-1)(T-2)/2 + K$ columns. Each column $\mathbf{z}_c$ of $\mathbf{Z}_i$ satisfies the moment condition $E(\mathbf{z}_c' \boldsymbol{\eta}_i^d) = 0$.

System GMM

Blundell and Bond (1998) proposed a system GMM estimator that uses additional moment conditions to increase efficiency. The efficiency gain can be substantial when there is strong serial correlation in the dependent variable.

When either ϕ is near 1 or $\sigma_v^2/\sigma_\epsilon^2$ is large, the lagged dependent variables $(y_{i1}, \dots, y_{i, t-2})$ are weak instruments for the differenced variable $\Delta y_{i, t-1}$. System GMM solves the weak instrument problem by augmenting the difference equations described previously with a set of *level equations*. When $L = K = 1$, the level equations are

$$\mathbf{y}_i^\ell = \mathbf{X}_i^\ell \boldsymbol{\gamma} + \boldsymbol{\epsilon}_i^\ell$$

where

$$\mathbf{y}_i^\ell = \begin{pmatrix} y_{i2} \\ y_{i3} \\ \vdots \\ y_{iT} \end{pmatrix} \quad \mathbf{X}_i^\ell = \begin{pmatrix} y_{i1} & x_{i2} \\ y_{i2} & x_{i3} \\ \vdots & \vdots \\ y_{i, T-1} & x_{iT} \end{pmatrix} \quad \boldsymbol{\epsilon}_i^\ell = \begin{pmatrix} v_i + \epsilon_{i2} \\ v_i + \epsilon_{i3} \\ \vdots \\ v_i + \epsilon_{iT} \end{pmatrix}$$

Blundell and Bond (1998) note that you can use lagged differences of y as instruments for the levels of y . The main instrument matrix for the level equations is then

$$\mathbf{Z}_i^\ell = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & \Delta y_{i2} & 0 & \cdots & 0 \\ 0 & 0 & \Delta y_{i3} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \Delta y_{i, T-1} \end{pmatrix}$$

where the first row corresponds to time $t = 2$. You can extend this to $L > 1$ and $K > 1$ by adding columns to $\mathbf{X}_i^\ell$ and elements to $\boldsymbol{\gamma}$ as appropriate. Higher-order lags require deletion of the leading rows of $\mathbf{y}_i^\ell$, $\mathbf{X}_i^\ell$, $\boldsymbol{\epsilon}_i^\ell$, and $\mathbf{Z}_i^\ell$.

Regression on the full system is obtained by stacking $\mathbf{y}_i^d$ and $\mathbf{y}_i^\ell$ to form $\mathbf{y}_i^s$, stacking $\mathbf{X}_i^d$ and $\mathbf{X}_i^\ell$ to form $\mathbf{X}_i^s$, and stacking $\boldsymbol{\eta}_i^d$ and $\boldsymbol{\epsilon}_i^\ell$ to form $\boldsymbol{\epsilon}_i^s$.

When you specify the DYNSSYS model option, the default instrument matrix for the full system is

$$\mathbf{Z}_i = \begin{pmatrix} \mathbf{Z}_i^d & \mathbf{0} & \mathbf{D}_i \\ \mathbf{0} & \mathbf{Z}_i^\ell & \mathbf{0} \end{pmatrix}$$

Estimation

The estimation in this section assumes system GMM. To obtain difference GMM, restrict estimation to the rows that correspond to the difference equations.

The initial moment matrix is derived from the theoretical variance of the combined residuals and is expressed as $\mathbf{H}_{1i} = \text{diag}(\mathbf{G}_{1i}, \mathbf{G}_{2i})$, where

$$\mathbf{G}_{1i} = \begin{pmatrix} 1 & -0.5 & 0 & \cdots & 0 & 0 & 0 \\ -0.5 & 1 & -0.5 & \cdots & 0 & 0 & 0 \\ 0 & -0.5 & 1 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & \cdots & 1 & -0.5 & 0 \\ 0 & 0 & 0 & \cdots & -0.5 & 1 & -0.5 \\ 0 & 0 & 0 & \cdots & 0 & -0.5 & 1 \end{pmatrix}$$

and $\mathbf{G}_{2i}$ is 0.5 times the identity matrix.

Define the weighting matrix as

$$\mathbf{W}_1 = \left(\sum_{i=1}^N \mathbf{Z}_i' \mathbf{H}_{1i} \mathbf{Z}_i \right)^{-1}$$

and define the projections as

$$\mathbf{P}_y = \sum_{i=1}^N \mathbf{Z}_i' \mathbf{y}_i^s; \quad \mathbf{P}_x = \sum_{i=1}^N \mathbf{Z}_i' \mathbf{X}_i^s$$

The one-step GMM estimate of $\boldsymbol{\gamma}$ is the weighted OLS estimator

$$\hat{\boldsymbol{\gamma}}_1 = \left(\mathbf{P}_x' \mathbf{W}_1 \mathbf{P}_x \right)^{-1} \mathbf{P}_x' \mathbf{W}_1 \mathbf{P}_y$$

The variance of $\hat{\boldsymbol{\gamma}}_1$ is

$$\text{Var}(\hat{\boldsymbol{\gamma}}_1) = \hat{\sigma}_\epsilon^2 \left(\mathbf{P}_x' \mathbf{W}_1 \mathbf{P}_x \right)^{-1}$$

where $\hat{\sigma}_\epsilon^2$ is the mean square error (MSE) that is derived solely from the difference equations, namely

$$\hat{\sigma}_\epsilon^2 = (M - K)^{-1} \sum_{i=1}^N \left(\mathbf{y}_i^d - \mathbf{X}_i^d \hat{\boldsymbol{\gamma}}_1 \right)' \left(\mathbf{y}_i^d - \mathbf{X}_i^d \hat{\boldsymbol{\gamma}}_1 \right)$$

The total number of observations, M , is equal to the number of observations for which the difference equations hold.

A disadvantage of $\hat{\boldsymbol{\gamma}}_1$ is its reliance on the theoretical basis of $\mathbf{H}_{1i}$. The two-step GMM estimate of $\boldsymbol{\gamma}$ replaces $\mathbf{H}_{1i}$ with a version that is obtained from the observed one-step residuals. Let $\mathbf{H}_{2i}$ be the outer product of $\hat{\boldsymbol{\epsilon}}_i^s = \mathbf{y}_i^s - \mathbf{X}_i^s \hat{\boldsymbol{\gamma}}_1$. Then

$$\hat{\boldsymbol{\gamma}}_2 = \left(\mathbf{P}_x' \mathbf{W}_2 \mathbf{P}_x \right)^{-1} \mathbf{P}_x' \mathbf{W}_2 \mathbf{P}_y$$

where

$$\mathbf{W}_2 = \left(\sum_{i=1}^N \mathbf{Z}_i' \mathbf{H}_{2i} \mathbf{Z}_i \right)^{-1}$$

The variance of $\hat{\boldsymbol{\gamma}}_2$ is

$$\text{Var}(\hat{\boldsymbol{\gamma}}_2) = \left(\mathbf{P}_x' \mathbf{W}_2 \mathbf{P}_x \right)^{-1}$$

Robust variances are calculated by the sandwich method. The robust variance of $\hat{\boldsymbol{\gamma}}_1$ is

$$\text{Var}^r(\hat{\boldsymbol{\gamma}}_1) = \left(\mathbf{P}_x' \mathbf{W}_1 \mathbf{P}_x \right)^{-1} \mathbf{P}_x' \mathbf{W}_1 \mathbf{W}_2^{-1} \mathbf{W}_1 \mathbf{P}_x \left(\mathbf{P}_x' \mathbf{W}_1 \mathbf{P}_x \right)^{-1}$$

The robust variance of $\hat{\boldsymbol{\gamma}}_2$ is

$$\text{Var}^r(\hat{\boldsymbol{\gamma}}_2) = \left(\mathbf{P}_x' \mathbf{W}_2 \mathbf{P}_x \right)^{-1} \mathbf{P}_x' \mathbf{W}_2 \mathbf{W}_3^{-1} \mathbf{W}_2 \mathbf{P}_x \left(\mathbf{P}_x' \mathbf{W}_2 \mathbf{P}_x \right)^{-1}$$

where

$$\mathbf{W}_3 = \left(\sum_{i=1}^N \mathbf{Z}_i' \mathbf{H}_{3i} \mathbf{Z}_i \right)^{-1}$$

and $\mathbf{H}_{3i}$ is the outer product of $\mathbf{y}_i^s - \mathbf{X}_i^s \hat{\boldsymbol{\gamma}}_2$.

Arellano and Bond (1991), among others, note that robust two-step variance estimators are biased. Windmeijer (2005) derived a bias-corrected variance of $\hat{\boldsymbol{\gamma}}_2$; you can obtain this correction by specifying the `BIASCORRECTED` option in the `MODEL` statement.

Define the one-step and two-step residuals as $\hat{\mathbf{e}}_{1i} = \mathbf{y}_i^s - \mathbf{X}_i^s \hat{\boldsymbol{\gamma}}_1$ and $\hat{\mathbf{e}}_{2i} = \mathbf{y}_i^s - \mathbf{X}_i^s \hat{\boldsymbol{\gamma}}_2$, respectively. Also define the projected two-step residual as

$$\mathbf{P}_e = \sum_{i=1}^N \mathbf{Z}_i' \hat{\mathbf{e}}_{2i}$$

Formulate the matrix $\mathbf{D}$ such that its k th column is $\mathbf{D}_k = \mathbf{V}_2 \mathbf{P}_x' \mathbf{W}_2 \mathbf{F}_k \mathbf{W}_2 \mathbf{P}_e$, where $\mathbf{V}_2 = \text{Var}(\hat{\boldsymbol{\gamma}}_2)$. The matrix $\mathbf{F}_k$ is the quadratic form

$$\mathbf{F}_k = \sum_{i=1}^N \mathbf{Z}_i' \left(\mathbf{x}_{ik} \hat{\mathbf{e}}_{1i}' + \hat{\mathbf{e}}_{1i} \mathbf{x}_{ik}' \right) \mathbf{Z}_i$$

where $\mathbf{x}_{ik}$ is the k th column of $\mathbf{X}_i^s$.

The Windmeijer (2005) bias-corrected variance is

$$\text{Var}^w(\hat{\boldsymbol{\gamma}}_2) = \mathbf{V}_2 + \mathbf{D} \mathbf{V}_2 + \mathbf{V}_2 \mathbf{D}' + \mathbf{D} \mathbf{V}_1' \mathbf{D}'$$

where $\mathbf{V}_1'$ is the robust variance estimate of $\hat{\boldsymbol{\gamma}}_1$.

Estimating the Intercept

The intercept term vanishes when you take first differences and is thus identified only in the level equations. If you specify the DYNDIFF option in the MODEL statement and your model includes an intercept, then PROC CPANEL fits the model by using system GMM with the (default) instrumentation

$$\mathbf{Z}_i = \begin{pmatrix} \mathbf{Z}_i^d & \mathbf{D}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{j}_i \end{pmatrix}$$

where $\mathbf{j}_i$ is a column of ones. Because all the level instruments are zero except the constant, parameter estimates other than the intercept are unaffected by the added level equations.

If you specify the DYNDIFF option in the MODEL statement and your model does not include an intercept, then the level equations are excluded from the estimation.

If you specify the DYNSSYS option in the MODEL statement, then there is no issue regarding the intercept. Under the default instrument specification, if $\mathbf{X}_i^\ell$ includes an intercept, then the level instruments include an added column of ones. That is,

$$\mathbf{Z}_i = \begin{pmatrix} \mathbf{Z}_i^d & \mathbf{0} & \mathbf{D}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_i^\ell & \mathbf{0} & \mathbf{j}_i \end{pmatrix}$$

Customizing Instruments

When you specify the DYNSSYS option to perform system GMM, the default instrument matrix is

$$\mathbf{Z}_i = \begin{pmatrix} \mathbf{Z}_i^d & \mathbf{0} & \mathbf{D}_i & \mathbf{0} \\ \mathbf{0} & \mathbf{Z}_i^\ell & \mathbf{0} & \mathbf{c}_i \end{pmatrix}$$

where $\mathbf{c}_i$ is a column of ones or, if you specify the NOINT option, $\mathbf{c}_i$ is $\mathbf{0}$.

You can override the default set of instruments by specifying the ENDOGENOUS, PREDTERMINED, and INSTRUMENTS statements. The following discussion assumes that you are performing system GMM by using the DYNSSYS option in the MODEL statement. When you specify the DYNDIFF option instead, any specification (except the constant $\mathbf{c}_i$) that pertains to the level equations is ignored.

Endogenous Variables

A variable x_{it} is endogenous if $E(x_{it} \epsilon_{is}) \neq 0$ for $s \leq t$ and 0 otherwise.

The ENDOGENOUS statement specifies a list of endogenous variables that are used to form instrument matrices. For the difference equations, the instruments are “GMM-style” and mirror the form that is used in $\mathbf{Z}_i^d$ for the dependent variable. Suppose that the model includes one lag of the dependent variable ($L = 1$). Specifying the variable X in the ENDOGENOUS statement adds the following instruments to the difference equations:

$$\mathbf{G}_i^d = \begin{pmatrix} x_{i1} & 0 & 0 & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & x_{i1} & x_{i2} & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & 0 & x_{i1} & x_{i2} & x_{i3} & 0 & \cdots & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & x_{i1} & \cdots & x_{i, T-2} \end{pmatrix}$$

The first row corresponds to time $t = 3$. The instruments are in lagged levels.

For the level equations, the ENDOGENOUS statement produces instruments that mirror the form used in $\mathbf{Z}_i^\ell$ for the dependent variable. Suppose that the model includes one lag of the dependent variable ($L = 1$). Specifying the variable X in the ENDOGENOUS statement adds the following instruments to the level equations:

$$\mathbf{G}_i^\ell = \begin{pmatrix} 0 & 0 & 0 & \cdots & 0 \\ 0 & \Delta x_{i2} & 0 & \cdots & 0 \\ 0 & 0 & \Delta x_{i3} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \Delta x_{i, T-1} \end{pmatrix}$$

The first row corresponds to time $t = 2$. Because the instruments are used for the level equations, they are in lagged differences.

By default, the ENDOGENOUS statement generates instruments for both the difference equations and the level equations. You can specify the EQ=DIFF option to generate instruments for only the difference equations. You can specify the EQ=LEVEL option to generate instruments for only the level equations.

The following code fits a dynamic panel model by using difference equations. It includes GMM-style instruments for both the dependent variable Sales and the regression variable Price.

```
proc cpanel data = mylib.a;
  id State Year;
  endogenous Sales Price / eq = diff;
  model Sales = Price PopDensity / dyndiff;
run;
```

Predetermined Variables

A variable x_{it} is predetermined if $E(x_{it}\epsilon_{is}) \neq 0$ for $s < t$ and 0 otherwise.

The PREDETERMINED statement specifies a list of predetermined variables that are used to form instrument matrices. For the difference equations, the instruments are similar to those that are formed for endogenous variables, except that each observation contains an extra instrument that reflects orthogonality in the current time period. If $L = 1$, specifying the variable X in the PREDETERMINED statement adds the following instruments to the difference equations:

$$\mathbf{P}_i^d = \begin{pmatrix} x_{i1} & x_{i2} & 0 & 0 & 0 & 0 & \cdots & 0 & 0 & 0 \\ 0 & 0 & x_{i1} & x_{i2} & x_{i3} & 0 & \cdots & 0 & 0 & 0 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots & \ddots & \vdots & \vdots & \vdots \\ 0 & 0 & 0 & 0 & 0 & 0 & 0 & x_{i1} & \cdots & x_{i, T-1} \end{pmatrix}$$

The first row corresponds to time $t = 3$.

For the level equations, the PREDETERMINED statement produces instruments that are similar to those in $\mathbf{Z}_i^\ell$, except that the lag is shifted up to reflect orthogonality in the current time period. If $L = 1$, specifying the variable X in the PREDETERMINED statement adds the following instruments to the level equations:

$$\mathbf{P}_i^\ell = \begin{pmatrix} \Delta x_{i2} & 0 & 0 & \cdots & 0 \\ 0 & \Delta x_{i3} & 0 & \cdots & 0 \\ 0 & 0 & \Delta x_{i4} & \cdots & 0 \\ \vdots & \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & 0 & \cdots & \Delta x_{i, T} \end{pmatrix}$$

The first row corresponds to time $t = 2$.

By default, the `PREDETERMINED` statement generates instruments for both the difference equations and the level equations. You can specify the `EQ=DIFF` option to generate instruments for only the difference equations. You can specify the `EQ=LEVEL` option to generate instruments for only the level equations.

The following code fits a dynamic panel model by using difference equations. The instrument set includes GMM-style instruments for both the endogenous dependent variable `Sales` and the predetermined regression variable `Price`.

```
proc cpanel data = mylib.a;
  id State Year;
  endogenous Sales / eq = diff;
  predetermined Price / eq = diff;
  model Sales = Price PopDensity / dyndiff;
run;
```

Exogenous Variables (Standard Instruments)

Exogenous variables are uncorrelated with both the level residuals and the differenced residuals. If a regression variable is exogenous, you might want to include that variable in the instrument set as a standard instrument. The `INSTRUMENTS` statement specifies a list of variables to be included as standard instruments.

For the difference equations, the standard instruments form the matrix $\mathbf{D}_i$, as described in the section “[First Differencing](#)” on page 512. These variables are usually exogenous regressors that you want to preserve under the projection to the instrument space. Because these instruments belong to the difference equations, the variables are automatically differenced.

For the level equations, the standard instruments are left untransformed. They usually correspond to external instruments that are not part of the main regression but that can be used as instruments for the regression variables in levels. If $L = 1$, specifying the `X1` and `X2` variables in the `INSTRUMENTS` statement adds the following instruments to the level equations:

$$\mathbf{L}_i = \begin{pmatrix} x_{i21} & x_{i22} \\ x_{i31} & x_{i32} \\ \vdots & \vdots \\ x_{iT1} & x_{iT2} \end{pmatrix}$$

The first row corresponds to time $t = 2$.

By default, the `INSTRUMENTS` statement generates instruments for both the difference equations and the level equations. You can specify the `EQ=DIFF` option to generate instruments for only the difference equations. You can specify the `EQ=LEVEL` option to generate instruments for only the level equations.

The following example illustrates how you would use the `ENDOGENOUS` and `INSTRUMENTS` statements to obtain the default set of instruments for system GMM:

```
proc cpanel data = mylib.a;
  id State Year;
  endogenous Sales / eq = both;
  instruments Price PopDensity / eq = diff;
  model Sales = Price PopDensity / dynsys;
run;
```

Note that the standard instruments for `Price` and `PopDensity` are included only in the difference equations.

Limiting the Number of Instruments

Arellano and Bond's (1991) technique of expanding instruments is a useful method of dealing with autocorrelation in the response variable. However, using too many instruments can bias the estimator. The number of instruments grows quadratically with the number of time periods, making computations less feasible for larger T .

By default, PROC CPANEL uses all available lags. You can limit the number of instruments by specifying the MAXBAND= option in the MODEL statement. For example, specifying MAXBAND=5 limits the number of GMM-style instruments to five per observation, for each variable. The MAXBAND= option applies to all GMM-style instruments: those from the ENDOGENOUS statement and those from the PREDETERMINED statement.

Sargan Test of Overidentifying Restrictions

A Sargan test is a referendum on your choice of instruments in a dynamic panel model. The Sargan test statistic for one-step GMM is

$$J = \frac{1}{\hat{\sigma}_\epsilon^2} \left(\sum_{i=1}^N \mathbf{Z}_i' \hat{\epsilon}_{1i} \right)' \mathbf{W}_1 \left(\sum_{i=1}^N \mathbf{Z}_i' \hat{\epsilon}_{1i} \right)$$

The Sargan test statistic for two-step GMM is

$$J = \left(\sum_{i=1}^N \mathbf{Z}_i' \hat{\epsilon}_{2i} \right)' \mathbf{W}_2 \left(\sum_{i=1}^N \mathbf{Z}_i' \hat{\epsilon}_{2i} \right)$$

The null hypothesis of the Sargan test is that the moment conditions (as defined by the columns $\mathbf{Z}_i$) hold, and thus $\mathbf{Z}_i$ form an adequate set of instruments. Under the null, J is distributed as χ^2 with degrees of freedom equal to the rank of $\mathbf{W}_c$ ($c = 1, 2$) minus the number of parameters K . The nominal rank of $\mathbf{W}_c$ is equal to the number of instruments. However, this number can be reduced because of collinearity and redundancy in the instrument specification. Furthermore, the maximum rank of $\mathbf{W}_2$ is N , regardless of the number of instruments.

You should treat Sargan tests with caution when robust variances are used in the estimation. The theoretical distribution of J does not hold under conditions that favor robust variances.

AR(m) Tests

An AR(m) test is a test for autocorrelation of order m in the model residuals. Let $\mathbf{R}_i^s$ be the working variance of the residuals from the full system. The precise definition of $\mathbf{R}_i^s$ depends on the GMM stage and whether robust variances are specified. Table 11.4 provides detailed definitions.

Table 11.4 Definitions of the Working Residual Variance

Estimator	$\mathbf{R}_i^s$
One-step	$\hat{\sigma}_\epsilon^2 \mathbf{H}_{1i}$
One-step, robust	$\mathbf{H}_{2i}$
Two-step	$\mathbf{H}_{2i}$
Two-step, robust	$\mathbf{H}_{3i}$

Define the residual vector

$$\hat{\mathbf{e}}_i = \begin{pmatrix} \hat{\eta}_i^d \\ \mathbf{0} \end{pmatrix}$$

where $\hat{\eta}_i^d = \mathbf{y}_i^d - \mathbf{X}_i^d \hat{\boldsymbol{\gamma}}_c$ are the residuals from the difference equations, evaluated at the final estimate of $\hat{\boldsymbol{\gamma}}_c$. The trailing zeros correspond to the level equations. Define $\hat{\boldsymbol{\omega}}_{mi}$ as a lagged version of $\hat{\mathbf{e}}_i$ such that the following statements are true:

1. The first m elements of $\hat{\boldsymbol{\omega}}_{mi}$ are 0.
2. The next $p - m$ elements of $\hat{\boldsymbol{\omega}}_{mi}$ are the first $p - m$ elements of $\hat{\mathbf{e}}_i$, where p is the number of difference equations.
3. The trailing elements of $\hat{\boldsymbol{\omega}}_{mi}$ that correspond to the level equations are 0.

Define the following:

$$\begin{aligned} \mathbf{P}_m &= \sum_{i=1}^N \mathbf{Z}_i' \mathbf{R}_i^s \hat{\boldsymbol{\omega}}_{mi} \\ \mathbf{Q}_m &= \sum_{i=1}^N \hat{\boldsymbol{\omega}}_{mi}' \mathbf{X}_i^s \end{aligned}$$

The AR(m) test statistic is $Z_m = k_{0m} \{k_{1m} + k_{2m} + k_{3m}\}^{-1/2}$, where

$$\begin{aligned} k_{0m} &= \sum_{i=1}^N \hat{\boldsymbol{\omega}}_{mi}' \hat{\mathbf{e}}_i \\ k_{1m} &= \sum_{i=1}^N \hat{\boldsymbol{\omega}}_{mi}' \mathbf{R}_i^s \hat{\boldsymbol{\omega}}_{mi} \\ k_{2m} &= -2\mathbf{Q}_m (\mathbf{P}_x' \mathbf{W}_c \mathbf{P}_x)^{-1} \mathbf{P}_x' \mathbf{W}_c \mathbf{P}_m \\ k_{3m} &= \mathbf{Q}_m \mathbf{V} \mathbf{Q}_m' \end{aligned}$$

The matrix $\mathbf{V}$ is the estimated variance matrix of the parameters, corresponding to the GMM stage that is specified, and either model-based, robust, or bias-corrected.

Under the null hypothesis of no autocorrelation, Z_m follows a standard normal distribution. Because of the differencing in the errors, well-specified models present autocorrelation of order $m = 1$, but any autocorrelation at higher orders indicates a violation of assumptions.

Poolability Test for Fixed Effects

A poolability test is an F test of the null hypothesis that all fixed effects are jointly 0; it is obtained by comparing fixed-effects estimates to those from pooled regression. The F statistic is

$$F = \frac{(\text{SSE}_r - \text{SSE}_u) / df_1}{\text{SSE}_u / df_2} \sim F(df_1, df_2)$$

where SSE_r is the error sum of squares from the restricted model (pooled regression) and SSE_u is the error sum of squares from the unrestricted fixed-effects model.

The numerator degrees of freedom, df_1 , equals $N - 1$ for one-way models and $(N - 1) + (T - 1)$ for two-way models. The denominator degrees of freedom, df_2 , is equal to the error degrees of freedom from the fixed-effects estimation. If you specify the NOINT option, add 1 to df_1 to account for the added restriction to the pooled regression.

Hausman Specification Tests

For models that include random effects, the CPANEL procedure outputs the results of the Hausman (1978) specification test. This test was also proposed by Wu (1973) and further extended in Hausman and Taylor (1982).

Consider two estimators, $\hat{\beta}_e$ and $\hat{\beta}_c$, which under the null hypothesis are both consistent but only $\hat{\beta}_e$ is asymptotically efficient. Under the alternative hypothesis, only $\hat{\beta}_c$ is consistent. The m statistic is

$$m = (\hat{\beta}_c - \hat{\beta}_e)' (\hat{\Sigma}_c - \hat{\Sigma}_e)^{-1} (\hat{\beta}_c - \hat{\beta}_e)$$

where $\hat{\Sigma}_c$ and $\hat{\Sigma}_e$ are estimates of the asymptotic covariance matrices of $\hat{\beta}_c$ and $\hat{\beta}_e$. The statistic m follows a χ^2 distribution with k degrees of freedom, where k is the rank of $(\hat{\Sigma}_c - \hat{\Sigma}_e)^{-1}$. This rank is normally equal to the dimension of $\hat{\beta}_c - \hat{\beta}_e$, but is reduced when regressors that are constant within cross sections are dropped from the fixed-effects model.

The null hypothesis is that the effects are independent of the regressors. Under the null hypothesis, the fixed-effects estimator is consistent yet inefficient, whereas the random-effects estimator is both consistent and efficient. Failure to reject the null hypothesis favors the random-effects specification.

Restricted Estimation

The CPANEL procedure can fit models that have linear restrictions, producing a Lagrange multiplier (LM) test for each restriction. Consider a set of J linear restrictions $\mathbf{R}\beta = \mathbf{q}$, where $\mathbf{R}$ is $J \times K$ and $\mathbf{q}$ is $J \times 1$.

The restricted regression is performed by minimizing the error sum of squares subject to the restrictions. In matrix terms, the Lagrangian for this problem is

$$L = (\mathbf{y} - \mathbf{X}\beta)'(\mathbf{y} - \mathbf{X}\beta) + 2\lambda(\mathbf{R}\beta - \mathbf{q})$$

The Lagrangian is minimized by the restricted estimator β^* , and it can be shown that

$$\beta^* = \hat{\beta} - (\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}'\lambda$$

where $\hat{\beta}$ is the unrestricted estimator.

Because $\mathbf{R}\beta^* = \mathbf{q}$, you can solve for λ to obtain the Lagrange multipliers

$$\lambda^* = \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1} (\mathbf{R}\hat{\beta} - \mathbf{q})$$

The standard errors of the Lagrange multipliers are the square roots of the diagonal elements of the variance matrix

$$\text{Var}(\lambda^*) = \hat{\sigma}_e^2 \left[\mathbf{R}(\mathbf{X}'\mathbf{X})^{-1}\mathbf{R}' \right]^{-1}$$

where $\hat{\sigma}_e^2$ is the mean square error (MSE) under the null hypothesis. A significant Lagrange multiplier indicates a restriction that is binding.

For each restriction, the Lagrange multiplier test is represented by a row in the parameter estimates table that displays the Lagrange multiplier, standard error, test statistic, and p -value. Although LM test statistics converge to a chi-square distribution under the null hypothesis, PROC CPANEL computes p -values by using the beta distribution, which is the exact distribution for finite samples.

Lagrange multiplier tests are not appropriate for instrumental variables regression and dynamic panel models. If you fit such a model, the linear restrictions are applied, but no formal test of their validity is performed.

Linear Hypothesis Testing

Consider a linear hypothesis of the form $\mathbf{R}\beta = \mathbf{q}$, where $\mathbf{R}$ is $J \times K$ and $\mathbf{q}$ is $J \times 1$. The Wald test statistic is

$$\chi_W^2 = (\mathbf{R}\hat{\beta} - \mathbf{q})' (\mathbf{R}\hat{\mathbf{V}}\mathbf{R}')^{-1} (\mathbf{R}\hat{\beta} - \mathbf{q})$$

where $\hat{\mathbf{V}}$ is the estimated variance of $\hat{\beta}$.

In simple linear models, the Wald test statistic is equal to the F test statistic

$$F = \frac{(\text{SSE}_r - \text{SSE}_u)/J}{\text{SSE}_u/df_e}$$

where SSE_r is the restricted error sum of squares, SSE_u is the unrestricted error sum of squares, and df_e is the unrestricted error degrees of freedom.

The F statistic represents a more direct comparison of the restricted model to the unrestricted model. Comparing error sums of squares is appealing in complex models for which restrictions are applied not only during the final regression but also during intermediate calculations.

The likelihood ratio (LR) test and the Lagrange multiplier (LM) test are derived from the F statistic. The LR test statistic is

$$\chi_{\text{LR}}^2 = M \ln \left[1 + \frac{JF}{M - K} \right]$$

The LM test statistic is

$$\chi_{\text{LM}}^2 = M \left[\frac{JF}{M - K + JF} \right]$$

The distribution of these test statistics is χ^2 with J degrees of freedom. The three tests are asymptotically equivalent, but they possess different small-sample properties. For more information, see Greene (2000, p. 392) and Davidson and MacKinnon (1993, pp. 456–458).

Heteroscedasticity-Corrected Covariance Matrices

The HCCME= option in the MODEL statement selects the type of heteroscedasticity-consistent covariance matrix. In the presence of heteroscedasticity, the covariance matrix has a complicated structure that can result in inefficiencies in the OLS estimates and biased estimates of the covariance matrix. The variances for cross-sectional and time dummy variables and the covariances with or between the dummy variables are not corrected for heteroscedasticity in the one-way and two-way models. Whether or not you specify the HCCME= option, these variances are the same. For the two-way models, the variance and the covariances for the intercept are not corrected.¹

Consider the following simple linear model:

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

This discussion parallels the discussion in Davidson and MacKinnon (1993, pp. 548–562). For panel data models, heteroscedasticity-corrected covariance matrix estimation (HCCME) is applied to the transformed data ($\tilde{\mathbf{y}}$ and $\tilde{\mathbf{X}}$). In other words, first the random or fixed effects are removed through transforming the data,² and then the heteroscedasticity (also autocorrelation with the HAC option) is corrected in the residual. The assumptions that make the linear regression best linear unbiased estimator (BLUE) are $E(\boldsymbol{\epsilon}) = 0$ and $E(\boldsymbol{\epsilon}\boldsymbol{\epsilon}') = \Omega$, where Ω has the simple structure $\sigma^2\mathbf{I}$. Heteroscedasticity results in a general covariance structure, and it is not possible to simplify Ω . The result is as follows:

$$\tilde{\boldsymbol{\beta}} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\mathbf{y} = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'(\mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}) = \boldsymbol{\beta} + (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\boldsymbol{\epsilon}$$

As long as the following is true, you are assured that the OLS estimate is consistent and unbiased:

$$\text{plim}_{n \rightarrow \infty} \left(\frac{1}{n} \mathbf{X}'\boldsymbol{\epsilon} \right) = 0$$

If the regressors are nonrandom, then it is possible to write the variance of the estimated $\boldsymbol{\beta}$ as

$$\text{Var}(\boldsymbol{\beta} - \tilde{\boldsymbol{\beta}}) = (\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\Omega\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1}$$

You can ameliorate the effect of structure in the covariance matrix by using generalized least squares (GLS), provided that Ω^{-1} can be calculated. Using Ω^{-1} , you premultiply both sides of the regression equation,

$$\mathbf{L}^{-1}\mathbf{y} = \mathbf{L}^{-1}\mathbf{X}\boldsymbol{\beta} + \mathbf{L}^{-1}\boldsymbol{\epsilon}$$

¹The dummy variables are removed by the within transformations, so their variances and covariances cannot be calculated the same way as the other regressors. They are recovered by the formulas in the sections “One-Way Fixed-Effects Model (FIXONE and FIXONETIME Options)” on page 494 and “Two-Way Fixed-Effects Model (FIXTWO Option)” on page 496. The formulas assume homoscedasticity, so they do not apply when HCCME is used. Therefore, standard errors, variances, and covariances are reported only when the HCCME= option is ignored. HCCME standard errors for dummy variables and intercept can be calculated by the dummy variable approach with the pooled model.

²For more information about transforming the data, see the sections “One-Way Fixed-Effects Model (FIXONE and FIXONETIME Options)” on page 494, “Two-Way Fixed-Effects Model (FIXTWO Option)” on page 496, “One-Way Random-Effects Model (RANONE Option)” on page 497, and “Two-Way Random-Effects Model (RANTWO Option)” on page 500.

where L denotes the Cholesky root of Ω (that is, $\Omega = LL'$ with L lower triangular).

The resulting GLS β is

$$\hat{\beta} = (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\mathbf{y}$$

Using the GLS β , you can write

$$\begin{aligned}\hat{\beta} &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\mathbf{y} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'(\Omega^{-1}\mathbf{X}_e + \Omega^{-1}\epsilon) \\ &= \beta + (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\epsilon\end{aligned}$$

The resulting variance expression for the GLS estimator is

$$\begin{aligned}\text{Var}(\beta - \hat{\beta}) &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\epsilon\epsilon'\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\mathbf{X}'\Omega^{-1}\Omega\Omega^{-1}\mathbf{X}(\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1} \\ &= (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}\end{aligned}$$

The difference in variance between the OLS estimator and the GLS estimator can be written as

$$(\mathbf{X}'\mathbf{X})^{-1}\mathbf{X}'\Omega\mathbf{X}(\mathbf{X}'\mathbf{X})^{-1} - (\mathbf{X}'\Omega^{-1}\mathbf{X})^{-1}$$

By the Gauss-Markov theorem, the difference matrix must be positive definite under most circumstances (zero if OLS and GLS are the same, when the usual classical regression assumptions are met). Thus, OLS is not efficient for a general error structure. It is crucial to realize that OLS does not produce biased results. It would suffice if you had a method of estimating a consistent covariance matrix and you used the OLS β . Estimation of the Ω matrix is certainly not simple. The matrix is square and has M^2 elements; unless some sort of structure is assumed, it becomes an impossible problem to solve. However, the heteroscedasticity can have quite a general structure. White (1980) shows that it is not necessary to have a consistent estimate of Ω . On the contrary, it suffices to calculate an estimate of the middle expression. That is, you need an estimate of

$$\Lambda = \mathbf{X}'\Omega\mathbf{X}$$

This matrix, Λ , is easier to estimate because its dimension is K . PROC CPANEL provides the following classical HCCME estimators for Λ . The approximation of the matrix depends on the value of the HCCME= option.

- HCCME=0

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

Here N is the number of cross sections and T_i is the number of observations in the i th cross section. The $\mathbf{x}_{it}'$ is from the t th observation in the i th cross section, constituting the $(\sum_{j=1}^{i-1} T_j + t)$ th row of the matrix $\mathbf{X}$. If you specify the CLUSTER option, one extra term is added to the preceding equation so that the estimator of matrix Λ is

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

The formula is the same as the formula for the robust variance matrix estimator in Wooldridge (2002, p. 152), and it is derived under the assumptions of section 7.3.2 of Wooldridge (2002). You can also obtain the preceding clustered standard error with HCCME=0 by specifying the ROBUST option alone.

- HCCME=1

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}'$$

Here M is the total number of observations, $\sum_{j=1}^N T_j$, and K is the number of parameters. If you specify the CLUSTER option, the estimator becomes

$$\frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \hat{\epsilon}_{it}^2 \mathbf{x}_{it} \mathbf{x}_{it}' + \frac{M}{M-K} \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \hat{\epsilon}_{it} \hat{\epsilon}_{is} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

This formula is similar to the formula for the robust variance matrix estimator in Wooldridge (2002, p. 152) with the heteroscedasticity adjustment term $M/(M-K)$.

- HCCME=2

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}'$$

The $\hat{h}_{it}$ term is the $(\sum_{j=1}^{i-1} T_j + t)$ th diagonal element of the hat matrix. The expression for $\hat{h}_{it}$ is $\mathbf{x}_{it}'(\mathbf{X}'\mathbf{X})^{-1}\mathbf{x}_{it}$. The hat matrix attempts to adjust the estimates for the presence of influence or leverage points. If you specify the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{1 - \hat{h}_{it}} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{\sqrt{1 - \hat{h}_{it}}} \frac{\hat{\epsilon}_{is}}{\sqrt{1 - \hat{h}_{is}}} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

This formula is similar to the formula for the robust variance matrix estimator in Wooldridge (2002, p. 152) with the heteroscedasticity adjustment.

- HCCME=3

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}'$$

If you specify the CLUSTER option, the estimator becomes

$$\sum_{i=1}^N \sum_{t=1}^{T_i} \frac{\hat{\epsilon}_{it}^2}{(1 - \hat{h}_{it})^2} \mathbf{x}_{it} \mathbf{x}_{it}' + 2 \sum_{i=1}^N \sum_{t=1}^{T_i} \sum_{s=1}^{t-1} \frac{\hat{\epsilon}_{it}}{1 - \hat{h}_{it}} \frac{\hat{\epsilon}_{is}}{1 - \hat{h}_{is}} (\mathbf{x}_{it} \mathbf{x}_{is}' + \mathbf{x}_{is} \mathbf{x}_{it}')$$

This formula is similar to the formula for the robust variance matrix estimator in Wooldridge (2002, p. 152) with the heteroscedasticity adjustment.

In their discussion, Davidson and MacKinnon (1993, p. 554) argue that the formula specified by HCCME=1 should always be preferred to the formula specified by HCCME=0. Although an HCCME= option value of 3 is generally preferred to 2, and 2 is preferred to 1, the calculation of HCCME=1 is as simple as the calculation of HCCME=0. Therefore, HCCME=1 is preferred when the calculation of the hat matrix is too tedious.

All HCCMEs have well-defined asymptotic properties. The small-sample properties are not well known, and you must exercise care when sample sizes are small.

The HCCME of $\text{Var}(\boldsymbol{\beta})$ is used to drive the covariance matrices for the fixed effects and the Lagrange multiplier standard errors. Robust estimates of the covariance matrix for $\boldsymbol{\beta}$ imply robust covariance matrices for all other parameters.

Heteroscedasticity- and Autocorrelation-Consistent Covariance Matrices

You use the HAC option in the MODEL statement to select the type of heteroscedasticity- and autocorrelation-consistent covariance matrix. As with the HCCME= option, an estimator of the middle expression Λ in sandwich form is needed. Define $g_{i,t} = x_{it}\epsilon_{it}$ as the gradient vector of the t th observation in the i th cross section. For the HAC option, it is estimated as

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \left(\sum_{t=1}^T g_{i,t} g'_{i,t} + \sum_{j=1}^{T-1} k\left(\frac{j}{b_i}\right) \sum_{t=1}^{T-j} (g_{i,t} g'_{i,t+j} + g_{i,t+j} g'_{i,t}) \right)$$

where $k(\cdot)$ is the real-valued kernel function, b_i is the bandwidth parameter for the i th cross section, and a is the adjustment factor of small-sample degrees of freedom (that is, $a = 1$ if you do not specify the ADJUSTDF option, and $a = NT/(NT - k)$ otherwise, where k is the number of parameters, including dummy variables). If the BANDWIDTH option is specified as a number, b_i is equal to the same number for every cross section. The types of kernel functions are listed in Table 11.5.

Table 11.5 Kernel Functions

Kernel Type	Equation
Bartlett	$k(x) = \begin{cases} 1 - x & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Parzen	$k(x) = \begin{cases} 1 - 6x^2 + 6 x ^3 & 0 \leq x \leq 1/2 \\ 2(1 - x)^3 & 1/2 \leq x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Quadratic spectral	$k(x) = \frac{25}{12\pi^2 x^2} \left(\frac{\sin(6\pi x/5)}{6\pi x/5} - \cos(6\pi x/5) \right)$
Truncated	$k(x) = \begin{cases} 1 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$
Tukey-Hanning	$k(x) = \begin{cases} (1 + \cos(\pi x))/2 & x \leq 1 \\ 0 & \text{otherwise} \end{cases}$

When you specify the BANDWIDTH=ANDREWS option, the bandwidth parameter is estimated as shown in Table 11.6.

Table 11.6 Bandwidth Parameter Estimation

Kernel Type	Bandwidth Parameter
Bartlett	$b_i = 1.1447(\alpha(1)T)^{1/3}$
Parzen	$b_i = 2.6614(\alpha(2)T)^{1/5}$
Quadratic spectral	$b_i = 1.3221(\alpha(2)T)^{1/5}$
Truncated	$b_i = 0.6611(\alpha(2)T)^{1/5}$
Tukey-Hanning	$b_i = 1.7462(\alpha(2)T)^{1/5}$

The values $\alpha(1)$ and $\alpha(2)$ are calculated separately for each cross section by using the following steps. Let g_{ait} denote the a th row of g_{it} , and let (ρ_a, σ_a^2) denote the corresponding estimates of the autoregressive and innovation variance parameters of the AR(1) model on $\{g_{ait}\}$, $a = 1, \dots, k$, where the AR(1) model is parameterized as $g_{ait} = \rho_a g_{ait-1} + \epsilon_{ait}$ with $\text{Var}(\epsilon_{ait}) = \sigma_a^2$. Notice that ρ_a and σ_a^2 are different for each cross section. Obtain $\alpha(1)$ and $\alpha(2)$ by using

$$\alpha(1) = \frac{\sum_{a=1}^k \frac{4\rho_a^2 \sigma_a^4}{(1-\rho_a)^6(1+\rho_a)^2}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}} \quad \alpha(2) = \frac{\sum_{a=1}^k \frac{4\rho_a^2 \sigma_a^4}{(1-\rho_a)^8}}{\sum_{a=1}^k \frac{\sigma_a^4}{(1-\rho_a)^4}}$$

When you specify BANDWIDTH=NEWKEYWEST94, according to Newey and West (1994) the bandwidth parameter is estimated as shown in Table 11.7.

Table 11.7 Bandwidth Parameter Estimation

Kernel Type	Bandwidth Parameter
Bartlett	$b_i = 1.1447(\{s_1/s_0\}^2 T)^{1/3}$
Parzen	$b_i = 2.6614(\{s_1/s_0\}^2 T)^{1/5}$
Quadratic spectral	$b_i = 1.3221(\{s_1/s_0\}^2 T)^{1/5}$
Truncated	$b_i = 0.6611(\{s_1/s_0\}^2 T)^{1/5}$
Tukey-Hanning	$b_i = 1.7462(\{s_1/s_0\}^2 T)^{1/5}$

The terms s_0 and s_1 are estimated separately for each cross section by using

$$s_0 = \sigma_0 + 2 \sum_{j=1}^n \sigma_j \quad s_1 = 2 \sum_{j=1}^n j \sigma_j$$

where n is the lag selection parameter and is determined by kernels for each cross section, as listed in Table 11.8.

Table 11.8 Lag Selection Parameter Estimation

Kernel Type	Lag Selection Parameter
Bartlett	$n = c(T/100)^{2/9}$
Parzen	$n = c(T/100)^{4/25}$

Table 11.8 *continued*

Kernel Type	Lag Selection Parameter
Quadratic spectral	$n = c(T/100)^{2/25}$
Truncated	$n = c(T/100)^{1/5}$
Tukey-Hanning	$n = c(T/100)^{1/5}$

The c in Table 11.8 is specified by the C= option; by default, C=12 for all cross sections.

The σ_j are estimated for the i th cross section by the equation

$$\sigma_j = T^{-1} \sum_{t=j+1}^T \left(\sum_{a=s}^k g_{ait} \sum_{a=s}^k g_{ait-j} \right), \quad j = 0, \dots, n$$

where g_{ait} is the same as in the Andrews method and s is 1 if you specify the NOINT option in the MODEL statement, and 2 otherwise.

When you specify BANDWIDTH=SAMPLESIZE, the bandwidth parameter is estimated by the equation

$$b_i = \begin{cases} \lfloor \gamma T^r + c \rfloor & \text{if the BANDWIDTH=SAMPLESIZE(INTSS) option is specified} \\ \gamma T^r + c & \text{otherwise} \end{cases}$$

where T is the sample size; $\lfloor x \rfloor$ is the largest integer less than or equal to x ; and γ , r , and c are values specified by the BANDWIDTH=SAMPLESIZE(GAMMA= RATE= CONSTANT=) options, respectively. These specified values are the same for every cross section.

If you specify the PREWHITENING option in the MODEL statement, g_{it} is prewhitened by the VAR(1) model,

$$g_{it} = A_i g_{it-1} + w_{it}$$

Then Λ_{HAC} is calculated by

$$\Lambda_{\text{HAC}} = a \sum_{i=1}^N \left\{ \left(\sum_{t=1}^T w_{it} w'_{it} + \sum_{t=1}^T \sum_{s=1}^{t-1} k\left(\frac{s-t}{b_i}\right) (w_{it} w'_{is} + w_{is} w'_{it}) \right) (I - A_i)^{-1} ((I - A_i)^{-1})' \right\}$$

For unbalanced data, the HAC option treats those missing values as 0.

R-Square

The R-square statistic is the proportion of variability in the dependent variable that is attributed to the independent variables. Because of the transformations that are used prior to fitting the final regression model, the conventional R-square measure is not appropriate for most of the models that the CPANEL procedure supports. In random-effects models that use a GLS transform, PROC CPANEL calculates the modified R-square statistic proposed by Buse (1973),

$$R^2 = 1 - \frac{\text{SSE}}{\mathbf{y}'\mathbf{D}'\hat{\mathbf{\Omega}}^{-1}\mathbf{D}\mathbf{y}}$$

where SSE is the error sum of squares from the final model fit, $\hat{\mathbf{\Omega}}^{-1/2}$ represents the GLS transform, and $\mathbf{D} = \mathbf{I}_M - a^{-1}\mathbf{J}_M\hat{\mathbf{\Omega}}^{-1}$, for $a = \mathbf{j}_M'\hat{\mathbf{\Omega}}^{-1}\mathbf{j}_M$.

In GLS models that do not have an intercept, the alternative R-square measure, which is attributed to Theil (1961), is calculated as follows:

$$R^2 = 1 - \frac{\text{SSE}}{\mathbf{y}'\hat{\mathbf{\Omega}}^{-1}\mathbf{y}}$$

In fixed-effects models, the R-square measure is

$$R^2 = 1 - \frac{\text{SSE}}{\mathbf{y}_w'\mathbf{y}_w}$$

where $\mathbf{y}_w$ is the within-transformed dependent variable.

In the case of pooled OLS estimation, all three of the R-square formulas reduce to the usual R-square statistic for linear models.

The R-square statistic is not appropriate for IV regression and dynamic panel estimation, and thus it is not reported for these models.

Displayed Output

The following sections describe the output that PROC CPANEL produces. The output is organized into various tables, which are discussed in their order of appearance.

Class Level Information

The “Class Level Information” table lists the levels of every variable specified in the **CLASS** statement. You should check this information to make sure that the data are correct. You can adjust the order of the **CLASS** variable levels by using the **ORDER=** option in the **CLASS** statement.

Model Description

The “Model Information” table displays basic information about the model: the response variable, the name of the data table, the estimation method, the number of observations, the number of cross sections, and the length of the time series. The reported numbers are useful for verifying that observations were not dropped unexpectedly and for verifying that the data are balanced when they should be.

Fit Statistics

The “Fit Statistics” table displays model fit statistics that are widely used in linear models. This table reports the error sum of squares, mean square error, root mean square error, R-square statistic, and the error degrees of freedom.

Variance Component Estimates

If you fit a model that contains random effects, then the “Variance Component Estimates” table reports the variances and standard deviations of the observation-level errors, the cross-sectional effects, and the time effects (in two-way models).

Test for Poolability

If you fit a fixed-effects model, then an F test of poolability is produced. The null hypothesis is that all fixed effects are jointly 0, making pooled OLS regression a viable alternative. The “F Test for No Fixed Effects” table reports the numerator degrees of freedom, denominator degrees of freedom, test statistic, and p -value.

Hausman Specification Tests

If you fit a model that contains random effects, then a table that summarizes the Hausman test is produced. The table presents the number of coefficients included in the test, the degrees of freedom, the m -statistic, and the p -value.

If you fit a one-way random-effects model (RANONE), then the fitted model is compared to the alternative model, a one-way fixed-effects (FIXONE) model.

If you fit a two-way random-effects model (RANTWO), then the fitted model is compared to the alternative model, a two-way fixed-effects (FIXTWO) model.

If you fit a Hausman-Taylor model (HTAYLOR), then the fitted model is compared to the alternative model, a one-way fixed-effects (FIXONE) model.

If you fit an Amemiya-MaCurdy model (AMACURDY), then the fitted model is compared to the alternative model, a Hausman-Taylor (HTAYLOR) model.

If you fit an instrumental variables random-effects model (IVRANONE), then the fitted model is compared to the alternative model, an IV fixed-effects (IVFIXONE) model.

Structural Summary

If you fit an instrumental variables (IV) model, then the “Structural Summary” table lists the endogenous effects and the instrumental variables.

Instruments

If you fit a dynamic panel model, then the “Instruments” table lists the instruments that are used and tallies the columns of the instruments matrix. The instruments are categorized by the type of equation (difference or level) and by the type of variable (endogenous, predetermined, or exogenous).

Sargan Test

If you fit a dynamic panel model, then the CPANEL procedure computes a Sargan test of overidentifying restrictions. This test is a referendum on your choice of instruments, and the null hypothesis is that your choice is adequate. The “Sargan Test” table reports the degrees of freedom, test statistic, and p -value.

Parameter Estimates

The parameter estimates, degrees of freedom, standard errors, t statistics and p -values for the hypothesis that the parameter is 0 are presented in the “Parameter Estimates” table. If one or more of your regression variables are labeled, then a column that contains variable labels is added to this table. Use the [NOLABEL](#) option in the MODEL statement to suppress this column.

If you specify a RESTRICT statement, then the table includes a row for each linear restriction. This row reports the restriction label, Lagrange multiplier (LM) statistic, standard error, t statistic, p -value, and a label that describes the restriction.

If you fit an instrumental variables (IV) model, then the table includes a column that identifies the endogenous variables. If you fit a Hausman-Taylor or Amemiya-MaCurdy model, then both the correlated variables and the time-invariant variables are identified in the table.

AR(m) Tests

If you fit a dynamic panel model, then the CPANEL procedure performs tests for autocorrelation in the residuals. In well-fitting models, you can expect some autocorrelation of lag order 1, but any autocorrelation at higher lags indicates a violation of assumptions. By default, AR tests for the first two lags are reported, but you can request tests for more lags by specifying the ARTESTS= option in the MODEL statement. For each test, the “AR(m) Test” table reports the lag, test statistic, and p -value.

Parameter Estimates Covariance Matrix

When you specify the [COVB](#) option in the [PROC CPANEL](#) statement, the CPANEL procedure displays the covariance matrix of the parameter estimates.

Parameter Estimates Correlation Matrix

When you specify the **CORRB** option in the **PROC CPANEL** statement, the CPANEL procedure displays the correlation matrix of the parameter estimates.

Tests of Linear Hypotheses

If you specify a **TEST** statement, a table that describes the tests is provided. For each test of hypothesis, the table reports the test label, the type of test (Wald, LR, or LM), the test statistic, the *p*-value, and a label that states the null hypothesis.

Model Comparison Tables

If you specify a **COMPARE** statement, two comparison tables are produced.

The first table is the “Comparison of Model Statistics” table, which lists the number of observations, number of cross sections, time series length, mean square error (MSE), root MSE, and R-square for each fitted model.

The second is table is the “Comparison of Model Parameter Estimates” table, which presents the parameter estimate and standard error of each regressor for each fitted model.

Both tables can be customized; for more information, see the section “**COMPARE Statement**” on page 472.

ODS Table Names

Each table that the CPANEL procedure creates has a name associated with it. You must use this name to refer to the table when you use ODS statements. These names are listed in [Table 11.9](#).

Table 11.9 ODS Tables Produced by PROC CPANEL

Table Name	Description	Statement	Option
ARTest	Autoregression tests for the residuals	MODEL	DYNDIFF or DYN SYS
ClassInfo	Level information from the CLASS statement	CLASS	Default
CorrB	Correlation matrix of parameter estimates	MODEL	CORRB
CovB	Covariance matrix of parameter estimates	MODEL	COVB
FitStatistics	Fit statistics	Default	
FixedEffectsTest	<i>F</i> test for poolability	MODEL	FIXONE, FIXONETIME, FIXTWO, or IVFIXONE
HausmanTestForRandom	Hausman test for random effects	MODEL	RANONE, RANTWO, IVRANONE, or IVRANTWO

Table 11.9 *continued*

Table Name	Description	Statement	Option
HausmanTestVsFixed	Hausman test for Hausman-Taylor models	MODEL	HTAYLOR
HausmanTestVsHausmanTaylor	Hausman test for Amemiya-MaCurdy models	MODEL	AMACURDY
Instruments	Instruments summary	MODEL	DYNDIFF or DYSYS
ModelDescription	Model summary and data counts	Default	
ParameterComparisonTable	Comparison of model parameter estimates, standard errors, and <i>t</i> tests	COMPARE	
ParameterEstimates	Solutions for the parameter estimates associated with effects in MODEL statements	Default	
ParameterEstimatesLegend	Legend that defines the abbreviations that were used in the parameter estimates table	Default	
SarganTest	Sargan test for overidentifying restrictions	MODEL	DYNDIFF or DYSYS
StatComparisonTable	Comparison of model summary statistics	COMPARE	
StructuralSummary	Endogenous and instrumental variable lists	MODEL	IVPOOLED, IVBTWNG, IVFIXONE, IV-FIXONETIME, IVFIXTWO, IVG2SLS, IVRANONE, or IVRANTWO
TestResults	Hypothesis tests of linear restrictions	TEST	
VarianceComponents	Variance component estimates	MODEL	RANONE, RANTWO, HTAYLOR, AMACURDY, IVRANONE, or IVRANTWO

Examples: CPANEL Procedure

Example 11.1: Airline Cost Data: Fixed Effects

The Christenson Associates airline data are a frequently cited data set (Greene 2000). The data measure the costs, prices of inputs, and utilization rates for six airlines from 1970 to 1984. This example analyzes the log transformations of cost (variable C), quantity (variable Q), and price (variable PF), and the untransformed load factor (variable LF). You speculate the following model,

$$\log(C_{it}) = \alpha + \beta_1 \log(Q_{it}) + \beta_2 \log(PF_{it}) + \beta_3 LF_{it} + v_i + \epsilon_{it}$$

where the v_i are airline effects. The actual model in the original, untransformed variables is highly nonlinear:

$$C_{it} = \exp(\alpha + \beta_3 LF_{it} + v_i + \epsilon_{it}) Q_{it}^{\beta_1} PF_{it}^{\beta_2}$$

The following statements create the data and perform the necessary log transformations. These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.airline;
  input Obs Airline T C Q PF LF;
  Year = T + 1969;
  lC   = log(C);
  lQ   = log(Q);
  lPF  = log(PF);
  label lC   = "Log Transformation of Costs";
  label lQ   = "Log Transformation of Quantity";
  label lPF  = "Log Transformation of Price of Fuel";
  label LF   = "Load Factor (utilization index)";
datalines;
1   1   1   1140640   0.95276   106650   0.53449
2   1   2   1215690   0.98676   110307   0.53233
3   1   3   1309570   1.09198   110574   0.54774
4   1   4   1511530   1.17578   121974   0.54085
5   1   5   1676730   1.16017   196606   0.59117
... more lines ...
```

The following statements fit a one-way fixed-effects model:

```
proc cpanel data = mylib.airline;
  id Airline Year;
  model lC = lQ lPF LF / fixone printfixed;
run;
```

Output 11.1.1 provides a model and data description. There are six cross sections and 15 time points.

Output 11.1.1 Airline Cost Data, Model Description

The CPANEL Procedure
One-Way Fixed Effects (FixOne)
Dependent Variable: IC (Log Transformation of Costs)

Model Description	
Estimation Method	FixOne
Variance Estimation	Model Based
Data Set	AIRLINE
Number of Observations	90
Number of Cross Sections	6
Time Series Length	15

The R-square and degrees of freedom can be seen in [Output 11.1.2](#). The R-square statistic nearly 1, indicating a reasonable fit. The error degrees of freedom is derived from 90 observations minus 5 cross sections, minus 4 regressors.

Output 11.1.2 Airline Cost Data, Fit Statistics

Fit Statistics			
SSE	0.2926	DFE	81
MSE	0.0036	Root MSE	0.0601
R-Square	0.9974		

The F test for fixed effects is shown in [Output 11.1.3](#). You easily reject the null hypothesis of poolability. There are significant effects due to airlines, and it would be unreasonable to perform pooled OLS regression that ignores these effects.

Output 11.1.3 Airline Cost Data, Test for Fixed Effects

F Test for No Fixed Effects				
Num DF	Den DF	F Value	Pr > F	
5	81	57.74	<.0001	

The PRINTFIXED option in the MODEL statement provides estimates of the airline effects (which are not displayed by default). Looking at the parameters, only two airlines (3 and 4) are significantly different from average. Quantity and fuel price have positive effects on cost, but load factors negatively affect costs. Because cost, quantity, and fuel price are log-transformed, the coefficients for quantity and price are interpreted as elasticities of cost. The coefficient for (log) fuel price is 0.417, meaning that you would associate a 10% increase in fuel price with a 4.17% increase in costs.

Output 11.1.4 Airline Cost Data, Parameter Estimates

Parameter Estimates						
Variable	DF	Estimate	Standard Error	t Value	Pr > t	Label
Intercept	1	9.713556	0.2296	42.30	<.0001	Intercept
IQ	1	0.919293	0.0299	30.76	<.0001	Log Transformation of Quantity
IPF	1	0.417492	0.0152	27.47	<.0001	Log Transformation of Price of Fuel
LF	1	-1.07044	0.2017	-5.31	<.0001	Load Factor (utilization index)
CS 1	1	-0.00759	0.0465	-0.16	0.8707	Cross-Sectional Effect: 1
CS 2	1	-0.04883	0.0390	-1.25	0.2144	Cross-Sectional Effect: 2
CS 3	1	-0.21651	0.0184	-11.77	<.0001	Cross-Sectional Effect: 3
CS 4	1	0.176971	0.0214	8.27	<.0001	Cross-Sectional Effect: 4
CS 5	1	0.016475	0.0378	0.44	0.6638	Cross-Sectional Effect: 5
CS 6	1	0.079484	0.0415	1.92	0.0588	Cross-Sectional Effect: 6

You suspect that there might be other factors at play, and so you augment your model to include time effects. The following statements fit a two-way model, a model with both airline and time effects:

```
proc cpanel data = mylib.airline;
  id Airline Year;
  model lC = lQ lPF LF / fixtwo printfixed;
run;
```

The F test and parameter estimates for the two-way model are provided in [Output 11.1.5](#).

Output 11.1.5 Airline Cost Data, Two-Way Fixed Effects

The CPANEL Procedure
Two-Way Fixed Effects (FixTwo)
Dependent Variable: IC (Log Transformation of Costs)

F Test for No Fixed Effects				
Num DF	Den DF	F Value	Pr > F	
19	67	23.10	<.0001	

Output 11.1.5 *continued*

Time 1979	1	0.091657	0.0811	1.13	0.2627	Time Effect: 1979
Time 1980	1	0.207197	0.1491	1.39	0.1693	Time Effect: 1980
Time 1981	1	0.28534	0.1756	1.62	0.1089	Time Effect: 1981
Time 1982	1	0.301255	0.1660	1.81	0.0741	Time Effect: 1982
Time 1983	1	0.300347	0.1536	1.96	0.0547	Time Effect: 1983
Time 1984	1	0.319001	0.1475	2.16	0.0341	Time Effect: 1984

Only a few of the time effects are significant, but there is an overall time trend of increasing costs. The time period of the data spans the OPEC oil embargoes and the dissolution of the Civil Aeronautics Board (CAB). These are two possible explanations for the rising costs.

A surprising result is that the fuel cost is not significant in the two-way model. If the time effects are proxies for the effect of the oil embargoes, then the effect of fuel price might be subsumed by the time effects. If the time dummy variables are proxies for the dissolution of the CAB, then the effect of load factors is not precisely estimated.

Example 11.2: Analyzing Demand for Liquid Assets: Random Effects

Feige (1964) provides data on the demand for liquid assets. The data are for six states and the District of Columbia (CA, DC, FL, IL, NY, TX, and WA) and were collected each year from 1949 to 1959. All variables are log-transformed.

The following statements create the `Assets` data table. These statements assume that your libref is named `mylib`, but you can substitute any appropriately defined libref.

```
data mylib.Assets;
  length state $ 2;
  input state $ year d t s y rd rt rs;
  label d = 'Per Capita Demand Deposits'
        t = 'Per Capita Time Deposits'
        s = 'Per Capita S & L Association Shares'
        y = 'Permanent Per Capita Personal Income'
        rd = 'Service Charge on Demand Deposits'
        rt = 'Interest on Time Deposits'
        rs = 'Interest on S & L Association Shares';
datalines;
CA  1949  6.2785  6.1924  4.4998  7.2056 -1.0700  0.1080  1.0664
CA  1950  6.4019  6.2106  4.6821  7.2889 -1.0106  0.1501  1.0767
CA  1951  6.5058  6.2729  4.8598  7.3827 -1.0024  0.4008  1.1291
CA  1952  6.4785  6.2729  5.0039  7.4000 -0.9970  0.4492  1.1227
CA  1953  6.4118  6.2538  5.1761  7.4200 -0.8916  0.4662  1.2110
CA  1954  6.4520  6.2971  5.3613  7.4478 -0.6951  0.4756  1.1924

... more lines ...
```

The data contain per capita consumptions for three liquid assets: demand deposits such as checking, time deposits, and savings and loan (S&L) shares. You posit a linear model for per capita demand deposits, with random effects for states.

The following statements fit a one-way random-effects model:

```
proc cpanel data = mylib.Assets;
  id state year;
  model d = y rd rt rs / ranone;
run;
```

The regression results are provided in [Output 11.2.1](#).

The “Variance Component Estimates” table provides the estimated variances and standard deviations for the cross-sectional (state) effects in addition to the overall errors. A majority of the overall error variance can be attributed to differences between states, not differences within states.

The “Hausman Test for Random Effects” table shows the result of a Hausman specification test. The null hypothesis is that state effects can be treated as random (random-effects model) and that they do not need to be estimated directly (fixed-effects model). The test results favor the random-effects specification that is used to generate this output.

Output 11.2.1 Demand for Demand Deposits, One-Way Random-Effects Model

The CPANEL Procedure
One-Way Random Effects (RanOne)
Swamy and Arora Variance Components
Dependent Variable: d (Per Capita Demand Deposits)

Model Description					
Estimation Method	RanOne				
Variance Estimation	Model Based				
Data Set	ASSETS				
Number of Observations	77				
Number of Cross Sections	7				
Time Series Length	11				

Fit Statistics			
SSE	0.0939	DFE	72
MSE	0.0013	Root MSE	0.0361
R-Square	0.7651		

Variance Component Estimates		
Source	Variance	Standard Deviation
Cross Sections	0.046394	0.215393
Error	0.00134	0.036608

Hausman Test For Random Effects				
Coefficients	DF	m	Value	Pr > m
	4	4	1.52	0.8235

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Pr > t
Intercept	1	-1.64325	0.6841	-2.40	0.0189
y	1	1.136776	0.0998	11.39	<.0001
rd	1	-0.26428	0.0517	-5.11	<.0001
rt	1	0.032076	0.0291	1.10	0.2746
rs	1	-0.41213	0.1192	-3.46	0.0009

The parameter estimate for the variable Y is greater than 1, indicating that demand is elastic to income—income has a more than proportional positive association with the demand for demand deposits. The coefficient on the variable RD indicates that demand deposits increase significantly as the service charge is reduced.

The variables RT and RS represent positive aspects of competing products, and you would expect these variables to affect demand negatively. The coefficient for RS meets that expectation, but the coefficient for RT is not significant.

The previous analysis used the default Swamy-Arora method to estimate the variance components. The CPANEL procedure supports four other methods, and you might be interested in how the different methods affect the analysis.

The following statements fit the model by using all five methods and include a COMPARE statement to compare the results:

```
proc cpanel data = mylib.Assets;
  id state year;
  sa: model d = y rd rt rs / ranone vcomp = sa;
  wh: model d = y rd rt rs / ranone vcomp = wh;
  wk: model d = y rd rt rs / ranone vcomp = wk;
  fb: model d = y rd rt rs / ranone vcomp = fb;
  nl: model d = y rd rt rs / ranone vcomp = nl;
  compare / mstat(varcs varerr);
run;
```

The tables produced by the COMPARE statement are provided in [Output 11.2.2](#).

Output 11.2.2 Comparison of Variance-Component Methods, Assets Data

**The CPANEL Procedure
Model Comparison**

Model: NL

Dependent Variable: d (Per Capita Demand Deposits)

Comparison of Model Statistics					
Statistic	SA RanOne	WH RanOne	WK RanOne	FB RanOne	NL RanOne
Var due to Cross Sections	0.0464	0.0315	0.0315	0.0291	0.0327
Var due to Error	0.001340	0.000107	0.001340	0.001340	0.001149

Comparison of Model Parameter Estimates					
Variable	SA RanOne	WH RanOne	WK RanOne	FB RanOne	NL RanOne
Intercept	Estimate -1.643246	-1.472425	-1.723092	-1.742581	-1.680406
	Std Err 0.684144	0.719067	0.681184	0.680541	0.682676
y	Estimate 1.136776	1.117252	1.145844	1.148051	1.141001
	Std Err 0.099816	0.099799	0.099776	0.099761	0.099802
rd	Estimate -0.264276	-0.245861	-0.272995	-0.275135	-0.268325
	Std Err 0.051729	0.052260	0.051445	0.051372	0.051600
rt	Estimate 0.032076	0.029227	0.033397	0.033718	0.032692
	Std Err 0.029138	0.028570	0.029416	0.029485	0.029266
rs	Estimate -0.412126	-0.414540	-0.410731	-0.410361	-0.411500
	Std Err 0.119181	0.117486	0.119968	0.120160	0.119548

You conclude that how you estimate variance components has little bearing on the regression results.

Example 11.3: Panel Study of Income Dynamics (PSID): Hausman-Taylor Models

Cornwell and Rupert (1988) analyze data from the Panel Study of Income Dynamics (PSID), an income study of 595 individuals over the seven-year period, 1976–1982 inclusive. Of particular interest is the effect of additional schooling on wages. The analysis here replicates that of Baltagi (2013, sec. 7.5), where it is surmised that covariate correlation with individual effects makes a standard random-effects model inadequate.

The following statements create the PSID data. These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.psid;
  input id t lwage wks south smsa ms exp exp2 occ ind union fem blk ed;
  label id      = 'Person ID'
        t       = 'Time'
        lwage   = 'Log of wages'
        wks     = 'Weeks worked'
        south   = '1 if resides in the South'
        smsa    = '1 if resides in SMSA'
        ms      = '1 if married'
        exp     = 'Years full-time experience'
        exp2    = 'exp squared'
        occ     = '1 if blue-collar occupation'
        ind     = '1 if manufacturing'
        union   = '1 if union contract'
        fem     = '1 if female'
        blk     = '1 if black'
        ed      = 'Years of education';
datalines;
1   1  5.5606799126  32  1  0  1  3   9   0  0  0  0  0  0  9
1   2  5.7203102112  43  1  0  1  4  16   0  0  0  0  0  0  9
1   3  5.9964499474  40  1  0  1  5  25   0  0  0  0  0  0  9

```

You begin by fitting a one-way random-effects model:

```
proc cpanel data = mylib.psid;
  id id t;
  model lwage = wks south smsa ms exp exp2 occ
              ind union fem blk ed / ranone;
run;
```

The output is shown in [Output 11.3.1](#). The coefficient on the variable ED (which represents years of education) estimates that an additional year of schooling is associated with about a 10% increase in wages. However, the results of the Hausman test for random effects show a serious violation of the random-effects assumptions, namely that the regressors are independent of the individual effects.

Output 11.3.1 One-Way Random Effects Estimation

The CPANEL Procedure

An alternative could be a fixed-effects (FIXONE) model, but that model would not permit estimation of the coefficient for ED, which does not vary within individuals. A compromise is the Hausman-Taylor model, for which you stipulate a set of covariates that are correlated with the individual effects (but uncorrelated with

the observation-level errors). You specify the correlated variables in the CORRELATED statement:

```
proc cpanel data = mylib.psid;
  id id t;
  model lwage = wks south smsa ms exp exp2 occ
              ind union fem blk ed / htaylor;
  correlated wks ms exp exp2 union ed;
run;
```

The results are shown in [Output 11.3.2](#). The table of parameter estimates has an added column, Type, which identifies the regressors that are assumed to be correlated with individual effects (C) and the regressors that do not vary within cross sections (TI). It was stated previously that the Hausman-Taylor model is a compromise between fixed-effects and random-effects models, and you can think of the compromise this way: You want to fit a random-effects model, but the correlated (C) variables make that model invalid. So you fall back to the consistent fixed-effects model, but then the time-invariant (TI) variables are the problem because they would be dropped from that model. The solution is to use the Hausman-Taylor estimator.

The estimation results show that an additional year of schooling is now associated with a 13.8% increase in wages. Also presented is a Hausman test that compares this model to the fixed-effects model. As was the case previously when you fit the random-effects model, you can think of the Hausman test as a referendum on the assumptions you are making. For this estimation, it seems that your choice of variables to treat as correlated is adequate.

Output 11.3.2 Hausman-Taylor Estimation

C: correlated with the individual effects

TI: constant (time-invariant) within cross sections

At its core, the Hausman-Taylor estimator is an instrumental variables regression, where the instruments are derived from regressors that are assumed to be uncorrelated with the individual effects. Technically, it is the cross-sectional means of these variables that need to be uncorrelated, not the variables themselves.

The Amemiya-MaCurdy model is a close relative of the Hausman-Taylor model. The only difference between the two is that the Amemiya-MaCurdy model makes the added assumption that the regressors (and not just their means) are uncorrelated with the individual effects. By making that assumption, the Amemiya-MaCurdy model can take advantage of a more efficient set of instrumental variables.

The following statements fit the Amemiya-MaCurdy model:

```
proc cpanel data = mylib.psid;
  id id t;
  model lwage = wks south smsa ms exp exp2 occ
               ind union fem blk ed / amacurdy;
  correlated wks ms exp exp2 union ed;
run;
```

The results are shown in [Output 11.3.3](#). Little is changed from the Hausman-Taylor model. The Hausman test compares the Amemiya-MaCurdy model to the Hausman-Taylor model (not the fixed-effects model as previously) and shows that the one additional assumption is acceptable. You even gained a bit of efficiency in the process; compare the standard deviations of the coefficient on the variable ED from both models.

Output 11.3.3 Amemiya-MaCurdy Estimation

C: correlated with the individual effects							
TI: constant (time-invariant) within cross sections							

Finally, you should realize that the Hausman-Taylor and Amemiya-MaCurdy estimators are not cure-alls for correlated individual effects. Estimation tacitly relies on the uncorrelated regressors being sufficient to predict the correlated regressors. Otherwise, you run into the problem of weak instruments. If you have weak instruments, you will obtain biased estimates that have very large standard errors. However, that does not seem to be the case here.

Example 11.4: Crime Rates in North Carolina: Instrumental Variables Regression

Cornwell and Trumbull (1994) examined data on crime rates from 90 counties in North Carolina and collected data each year from 1981 to 1987. The following statements create the Crime data table. These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.Crime;
  input county year west central urban d82 d83 d84 d85 d86 d87
        lcrmrte lprbarr lprbconv lprbpris lavgsen lpolpc
        ldensity ltaxpc lwcon lwtuc lwtrd lwfir lwser lwmfg
        lwfed lwsta lwloc lmix lpctymle lpctmin;
  label county      = 'county identifier'
        year        = '81 to 87'
        west        = '1 if in western N.C.'
        central     = '1 if in central N.C.'
        urban       = '1 if in SMSA'

  ... more lines ...
```

The variables are too numerous to describe individually, but they are fully labeled in the regression output and are summarized as follows:

- The panel ID variables are County and Year.
- The dependent variable, LCrMrtE, is the log of the crime rate (number of crimes divided by total population).
- The variables West, Central, and Urban provide geographical background for each county.
- The variables D82 through D87 are dummy variables for year effects.
- The variables with the LPrb prefix are log-probabilities of police or legal actions. For example, LPrbArr is the log-probability of an arrest given that a crime was committed.
- The variables with the LW prefix are log weekly wages for various occupations and industries.
- Other variables that begin with the letter L are log-transformed. For example, the variable LPolPC is the log of police per capita.

Cornwell and Trumbull (1994) fit a fixed-effects model for the log of crime rate, with the log-probability of arrest (LPrbArr), and the log of police per capita (LPolPC) among the regressors. They noted that these two regressors were endogenous because of the following causality loops:

- Although police presence might decrease the crime rate because of deterrence (or increase the crime rate because of better reporting), an increase in crime might cause a desire for more police presence.
- Although the crime rate might fall if more crimes resulted in arrest, a rising crime rate could cause the probability of arrest to decrease because police resources would be spread thin.

To deal with the endogeneity, Cornwell and Trumbull (1994) fit a two-stage least squares (2SLS) model with county-level fixed effects, with two external instruments: LTaxPC (log tax revenue per capita) and LMix (log ratio of crimes that involve face-to-face contact). Their rationale for using these instruments is that counties with higher tax revenues have more police presence and that face-to-face crimes have a higher probability of arrest because victims could identify their offenders.

Baltagi (2006) proposed a similar 2SLS model, but with random effects instead of fixed effects for counties. The following statements recreate that estimation:

```
proc cpanel data = mylib.crime;
  id county year;
  model lcrmte = lprbarr lpolpc lprbconv lprbpris lavgsen ldensity
               lwcon lwtuc lwtrd lwfir lwser lwmfg lwfed lwsta
               lwloc lpctymle lpctmin west central urban
               d82 d83 d84 d85 d86 d87 / ivranone;
  endogenous lprbarr lpolpc;
  instruments ltaxpc lmix;
run;
```

The results are shown in [Output 11.4.1](#). The output includes a “Structural Summary” table, which lists the endogenous variables and the instrumental variables. The list of instrumental variables includes both the specified external instruments (variables LTaxPC and LMix) and the exogenous regression variables.

EN: endogenous variable

Cornwell and Trumbull (1994) favored a fixed-effects approach because a Hausman specification test rejected the null hypothesis of random effects. Baltagi (2006) argued that the Hausman test used by Cornwell and Trumbull (1994) was inaccurate because it was based on standard methodology that did not account for endogeneity in the regressors.

Baltagi (2006) proposed a modified 2SLS Hausman test, and the results of that test are provided in the “Hausman Test For Random Effects” table in the output. The results favor the random-effects specification.

A higher probability of arrest is shown to diminish crime, and police presence increases the crime rate because more crimes are reported.

The following statements fit the model by two-step GMM with robust standard errors:

```
proc cpanel data = mylib.crime;
  id county year;
  model lcrmte = lprbarr lpolpc lprbconv lprbpris lavgsen ldensity
              lwcon lwtuc lwtrd lwfir lwser lwmfg lwfed lwsta
              lwloc lpctymle lpctmin west central urban
              d82 d83 d84 d85 d86 d87 / ivranone gmm = twostep
              robust;
  endogenous lprbarr lpolpc;
  instruments ltaxpc lmix;
run;
```

The results are shown in [Output 11.4.2](#). The coefficients do not change much, but the standard errors are now more reliable. You can also obtain bias-corrected standard errors by using the `BIASCORRECTED` option according to the method of Windmeijer (2005).

EN: endogenous variable

Example 11.5: Cigarette Sales Data: Dynamic Panel Estimation

Consider a dynamic panel demand model for cigarette sales that illustrates the methods described in the section “Dynamic Panel Estimation (DYNDIFF and DYNSSYS Options)” on page 511. The data are from a panel of 46 American states over the period 1963–1992. The dependent variable is the logarithm of per capita cigarette sales (variable LSales). Other factors that were measured include the log of price (LPrice), the log of disposable income (LDisp), and the log of minimum price in adjoining states (LMin). For a full description of the data, see Baltagi (2013, sec. 8.9).

The following statements create the Cigar data set. These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```

data mylib.Cigar;
  input State Year Price Pop Pop_16 Cpi Disp Sales Min;
  LSales = log(Sales);
  LPrice = log(Price);
  LDisp  = log(Disp);
  LMin   = log(Min);
  label
    State   = 'State abbreviation'
    Year    = 'Year'
    LSales  = 'Log cigarette sales in packs per capita'
    LPrice  = 'Log price per pack of cigarettes'
    LDisp   = 'Log per capita disposable income'
    LMin    = 'Log minimum price in adjoining states per pack of cigarettes';
datalines;

... more lines ...

```

You propose a panel model for cigarette sales that contains fixed effects for states. Because you believe that the data are insufficient to explain all possible shocks in yearly sales, you include lagged sales in the model as a regressor. By construction, lagged sales are an endogenous regressor, and you thus specify dynamic panel estimation by using the DYNDIFF option. The following statements fit the model:

```

proc cpanel data = mylib.Cigar;
  id State Year;
  model LSales = LPrice LDisp LMin / dyndiff;
run;

```

The results are shown in [Output 11.5.1](#). Note that it was not necessary to explicitly include lagged sales on the right-hand side of the model; PROC CPANEL generates it for you. The coefficient on lagged sales is 0.732, indicating a high degree of autocorrelation in the dependent variable. When cigarette sales are unusually high or low because of unforeseen circumstances, the effects tend to linger for several years. The results also show that demand is highly elastic to price.

Output 11.5.1 Dynamic Panel Estimation for Cigarette Sales

The CPANEL Procedure
Dynamic Panel Estimation Using Difference Equations (DynDiff)
Dependent Variable: LSales (Log cigarette sales in packs per capita)

Model Description						
Estimation Method	DynDiff					
Estimation Technique	One-Step GMM					
Variance Estimation	Model Based					
Data Set	CIGAR					
Number of Observations	1380					
Number of Cross Sections	46					
Time Series Length	30					
GMM Bandwidth	30					

Fit Statistics			
SSE	3.1373	DFE	1283
MSE	0.0024	Root MSE	0.0494

Instruments			
Type	Variables	Number of Instruments	
Difference Equations, Endogenous	LSales	406	
Difference Equations, Standard	LPrice LDisp LMin	3	
Level Equations, Standard	Intercept	1	
Total		410	

Sargan Test			
DF	Chi-Square	Pr > ChiSq	
405	712.45	<.0001	

Parameter Estimates						
Variable	DF	Estimate	Standard Error	t Value	Pr > t	Label
Intercept	1	0.769092	0.0658	11.69	<.0001	Intercept
LSales_1	1	0.732212	0.0178	41.07	<.0001	Lag 1: Log cigarette sales in packs per capita
LPrice	1	-0.26328	0.0255	-10.31	<.0001	Log price per pack of cigarettes
LDisp	1	0.166116	0.0105	15.88	<.0001	Log per capita disposable income
LMin	1	0.032726	0.0233	1.40	0.1604	Log minimum price in adjoining states per pack of cigarettes

AR(m) Tests		
Lag	Z	Pr > Z
1	-15.44	<.0001
2	2.47	0.0134

Included in [Output 11.5.1](#) are two diagnostic measures. The first, a Sargan test, is a test of the validity of the moment conditions that are conferred by the GMM instruments that were used. The p -value indicates that the moment conditions are not valid and that you should probably look for a set of instruments other than the default set that PROC CPANEL provides.

The second diagnostic test is the $AR(m)$ test for autocorrelation in the residuals. In well-fitting dynamic panel models, you expect to see some autocorrelation of lag 1, but any autocorrelation at higher lags indicates a poor fit. The autocorrelation at lag 2 is significant, leading you to seek a better-fitting alternative.

One possible explanation for the poor fit is that, by default, PROC CPANEL uses the one-step generalized method of moments (GMM). One-step GMM is known for being too reliant on the assumption that the residuals from the difference equations are not serially correlated. An alternative is two-step GMM, which instead uses a data-driven variance matrix for the differenced residuals.

The following statements fit the model by two-step GMM:

```
proc cpanel data = mylib.Cigar;
  id State Year;
  endogenous LSales;
  instruments LPrice LDisp LMin;
  model LSales = LPrice LDisp LMin / dyndiff gmm = twostep biascorrected;
run;
```

The code includes ENDOGENOUS and INSTRUMENTS statements that, for demonstration purposes, reproduce the default instrument set. That set includes the following:

- GMM-style instruments based on the endogenous dependent variable, LSales
- standard instruments for the exogenous regressors LPrice, LDisp, and LMin
- a column of ones in the instrument matrix for the level equations that corresponds to the model intercept

The code also includes the BIASCORRECTED option, which produces bias-corrected standard errors according to the method of Windmeijer (2005).

The results are shown in [Output 11.5.2](#). The coefficients do not change much, but the standard errors are now more reliable. The model diagnostic tests indicate a better fit, although you should use caution when interpreting Sargan test results. Sargan tests lack power when the number of instruments is large, and their distributional properties come into question under conditions that favor either robust or bias-corrected standard errors.

Output 11.5.2 Dynamic Panel Estimation by Two-Step GMM

The CPANEL Procedure Dynamic Panel Estimation Using Difference Equations (DynDiff) Dependent Variable: LSales (Log cigarette sales in packs per capita)

Model Description	
Estimation Method	DynDiff
Estimation Technique	Two-Step GMM
Variance Estimation	Windmeijer Bias Corrected
Data Set	CIGAR
Number of Observations	1380
Number of Cross Sections	46
Time Series Length	30
GMM Bandwidth	30

Output 11.5.2 *continued*

Fit Statistics					
SSE	3.1277	DFE	1283		
MSE	0.0024	Root MSE	0.0494		

Instruments		
Type	Variables	Number of Instruments
Difference Equations, Endogenous	LSales	406
Difference Equations, Standard	LPrice LDisp LMin	3
Level Equations, Standard	Intercept	1
Total		410

Sargan Test		
DF	Chi-Square	Pr > ChiSq
41	45.20	0.3008

Parameter Estimates					
Variable	DF	Estimate	Standard Error	t Value	Pr > t Label
Intercept	1	0.776914	0.1458	5.33	<.0001 Intercept
LSales_1	1	0.728347	0.0492	14.79	<.0001 Lag 1: Log cigarette sales in packs per capita
LPrice	1	-0.25707	0.0421	-6.11	<.0001 Log price per pack of cigarettes
LDisp	1	0.167345	0.0248	6.75	<.0001 Log per capita disposable income
LMin	1	0.025064	0.0432	0.58	0.5616 Log minimum price in adjoining states per pack of cigarettes

AR(m) Tests		
Lag	Z	Pr > Z
1	-5.00	<.0001
2	1.90	0.0575

The previous estimation treats regressors such as LPrice as exogenous. If you believe that price is endogenous, you can create GMM-style instruments for LPrice to replace the default standard instruments.

The following statements fit the model by using GMM-style instruments for LPrice:

```
proc cpanel data = mylib.Cigar;
  id State Year;
  endogenous LSales LPrice;
  instruments LDisp LMin;
  model LSales = LPrice LDisp LMin / dyndiff gmm = twostep biascorrected;
run;
```

The results are shown in [Output 11.5.3](#). Treating LPrice as endogenous nearly doubles the number of instruments. Although this is not the case here, when the number of instruments is so large that it makes estimation infeasible, you can limit the number of instruments by specifying the MAXBAND= option in the MODEL statement.

Output 11.5.3 Dynamic Panel Estimation, Custom Instrument Set

Overview: CQLIM Procedure

The CQLIM procedure analyzes univariate and multivariate limited dependent variable models in which dependent variables take discrete values or are observed within only a limited range of values. When the dependent variable takes discrete values, you can use either a logit model, a probit model, or an ordered logit or probit model, depending on the distribution of the dependent variable. In addition to the discrete variable models, the CQLIM procedure includes Tobit models, truncated regression models, and multivariate models. The multivariate model can contain discrete choice and limited dependent variables in addition to linear continuous dependent variables.

Another class of limited dependent variable models that the CQLIM procedure supports is stochastic frontier models. These models were first introduced by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977); they are capable of analyzing technical inefficiencies in production functions or cost functions.

The CQLIM procedure is similar to the QLIM procedure in SAS/ETS software; PROC CQLIM requires SAS Cloud Analytic Services (CAS) in order to run. Both procedures analyze univariate and multivariate limited dependent variable models. Unlike the QLIM procedure, which can run only on a single workstation, the CQLIM procedure takes advantage of the distributed computing environment of CAS, which enables it to distribute the optimization task to one or more nodes. In addition, each node can use one or more threads to perform the optimization on its subset of the data. When several nodes are used and each node uses several threads to carry out its part of the work, the result is a highly parallel computation that can provide a dramatic gain in performance.

The CQLIM procedure can use the maximum likelihood method or the Bayesian method to perform the inference of the available models. By default, it uses multiple threads to perform computations.

PROC CQLIM Features

The CQLIM procedure supports the following models:

- linear regression models with heteroscedasticity
- probit models with heteroscedasticity
- logit models with heteroscedasticity
- Tobit models with heteroscedasticity
- truncated regression models with heteroscedasticity
- bivariate probit models
- bivariate Tobit models
- multivariate limited dependent variables
- stochastic frontier production and cost models

In linear regression models with heteroscedasticity, the assumption that error variance is constant across observations is relaxed. The CQLIM procedure allows for a number of different linear and nonlinear variance specifications.

The CQLIM procedure is also capable of modeling problems in which the dependent variable takes discrete values. For these problems, you can use either a logit model or a probit model. In both cases, the dependent variable is modeled by using a binary distribution (typically, $y = 0, 1$). The main difference is that the logit model is characterized by an underlying logistic distribution, whereas the probit model has a Gaussian distribution. When the dependent variable takes more than two levels, the binary assumption is no longer valid. In these cases, you can use the ordered logit regression and the ordered probit regression. Assumptions about the error variance can also be relaxed in order to estimate a probit or logit model with heteroscedasticity.

PROC CQLIM also offers a class of models in which the dependent variable is censored or truncated from below, above, or both. When a continuous dependent variable is observed within only a certain range, and values outside this range are not available, PROC CQLIM offers a class of models that adjust for truncation. In some cases, the dependent variable is continuous within only a certain range, and all values outside this range are reported as being on its boundary. For example, if it is not possible to observe negative values, the value of the dependent variable is reported as equal to 0. Because the data are censored, ordinary least squares (OLS) results are inconsistent, and you cannot be certain that the predicted values from the model will fall in the appropriate region.

Most of the models in the CQLIM procedure can be extended to accommodate bivariate and multivariate scenarios.

The stochastic frontier production and cost models available in PROC CQLIM allow for random shocks of the production or cost. These models include a systematic positive component in the error term that adjusts for technical or cost inefficiency.

The CQLIM procedure can use the maximum likelihood method for both univariate and multivariate models. Initial starting values for the nonlinear optimizations are usually calculated by OLS. In addition, the CQLIM procedure can use the Bayesian method for univariate models, with the following exceptions: stochastic frontier models, models with heterogeneous variances, and ordinal models.

PROC CQLIM Compared with Other SAS Procedures

The CQLIM procedure provides limited dependent data modeling functionality comparable to that of the HPQLIM and QLIM procedures in SAS/ETS software.

PROC CQLIM Compared with the HPQLIM Procedure

The functionality of the CQLIM procedure closely resembles that of the HPQLIM procedure, which is a high-performance procedure. The CQLIM procedure is the next generation of the HPQLIM procedure, and it was developed specifically for SAS Viya. Both procedures are designed to run on a cluster of machines that distribute the data and the computations. Both procedures perform computations in multiple threads on multiple machines.

The CQLIM procedure supports maximum likelihood estimation of all the models available in PROC HPQLIM. It also supports Bayesian estimation of most single-equation models.

PROC CQLIM Compared with the QLIM Procedure

The CQLIM procedure is specifically designed to operate in SAS Viya and performs computations in multiple threads on multiple machines. The capability of the QLIM procedure to perform computations in a distributed environment is limited to the parallel implementation of Markov chain Monte Carlo sampling algorithms for Bayesian analysis.

This release of the CQLIM procedure contains some, but not all, of the functionality available in the QLIM procedure. PROC QLIM provides the following features, which are not available in PROC CQLIM:

- sample selection models
- variable selection
- Bayesian analysis for all models

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the mylib CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CQLIM Procedure

This example illustrates the use of the CQLIM procedure. The data were originally published by Mroz (1987), and the following DATA steps load a subset of the data. The assumption here is that your libref is named `mylib`, but you can substitute any appropriately defined libref.

;

data mylib.subset;
  set subset;
run;
```

In these data, `Hours` is the number of hours that a wife worked outside the household in a particular year, `Yrs_Ed` is years of education, and `Yrs_Exp` is years of work experience.

From the nature of the data, it is clear that there are a number of women who committed some positive number of hours to outside work ($y_i > 0$ is observed). There are also a number of women who did not work outside the household at all ($y_i = 0$ is observed). This yields the following model,

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$ and $\mathbf{x}_i$ denotes the set of explanatory variables. The following statements fit a Tobit model to the number of hours worked, with years of education and years of work experience as covariates:

```

/*-- Tobit Model --*/
proc cqlim data=mylib.subset;
  model hours = yrs_ed yrs_exp;
  endogenous hours ~ censored(lb=0);
run;

```

The output of the CQLIM procedure is shown in [Output 12.1](#).

Figure 12.1 Tobit Analysis Results

Estimating a Tobit Model

The CQLIM Procedure

Model Fit Summary	
Dependent Variable	Hours
Number of Observations	17
Data Set	SUBSET
Log Likelihood	-74.937
Maximum Absolute Gradient	6.748E-6
Number of Iterations	5
Optimization Method	Newton-Raphson
AIC	157.874
SBC	161.2069
Covariance Estimation	Hessian

Convergence criterion (ABSGCONV=0.00001) satisfied.

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	-5595.665232	27.645559	-202.41	<.0001
Yrs_Ed	1	372.981321	53.962540	6.91	<.0001
Yrs_Exp	1	63.319498	36.536554	1.73	0.0831
_Sigma	1	1582.240492	389.785175	4.06	<.0001

The “Parameter Estimates” table contains four rows. The first three rows correspond to the vector estimate of the regression coefficients β . The last row is called `_Sigma`, which corresponds to the estimate of the error variance σ .

Syntax: CQLIM Procedure

The following statements are available in the CQLIM procedure:

```

PROC CQLIM options ;
  BAYES <options> ;
  BOUNDS bound1 < , bound2 ... > ;
  BY variables ;
  CLASS variable <( options )> ... <variable <( options )>> </ global-options > ;
  DISPLAY <table-list> </ options > ;
  DISPLAYOUT table-spec-list </ options > ;
  FREQ variable ;
  ENDOGENOUS variables ~ options ;
  HETERO dependent-variables ~ exogenous-variables / options ;
  INIT initvalue1 < , initvalue2 ... > ;
  MODEL dependent-variables = regressors / options ;
  OUTPUT OUT=libref.data-table <output-options> ;
  PRIOR parameter-list ~ distribution ;
  RESTRICT restriction1 < , restriction2 ... > ;
  TEST options ;
  WEIGHT variable </ option > ;

```

At least one MODEL statement is required. If you specify more than one MODEL statement, the CQLIM procedure estimates a system of models. The BAYES statement is not compatible with multiple MODEL statements or with the BOUNDS, HETERO, RESTRICT, or TEST statement. If you specify more than one FREQ or WEIGHT statement, only the variable that is specified in the first instance of the statement is used.

Functional Summary

Table 12.1 summarizes the statements and options available in the CQLIM procedure.

Table 12.1 Functional Summary

Description	Statement	Option
Data Table Options		
Specifies the input data table	PROC CQLIM	DATA=
Writes predictions to an output data table	OUTPUT	OUT=
Declaring the Role of Variables		
Specifies BY-group processing	BY	
Specifies classification variables	CLASS	
Specifies a frequency variable	FREQ	
Specifies a weight variable	WEIGHT	NONNORMALIZE

Table 12.1 *continued*

Description	Statement	Option
Printing Control Options		
Prints the correlation matrix of the estimates	PROC CQLIM	CORRB
Prints the covariance matrix of the estimates	PROC CQLIM	COVB
Prints a summary iteration listing	PROC CQLIM	ITPRINT
Optimization Process Control Options		
Specifies the maximum number of iterations	PROC CQLIM	MAXITER=
Selects the iterative minimization method to use	PROC CQLIM	METHOD=
Sets boundary restrictions on parameters	BOUNDS	
Sets initial values for parameters	INIT	
Sets linear restrictions on parameters	RESTRICT	
Model Estimation Options		
Specifies the method to calculate parameter covariance	PROC CQLIM	COVEST=
Specifies the number of draws for Monte Carlo integration	PROC CQLIM	NDRAW=
Suppresses the intercept parameter	MODEL	NOINT
Specifies a seed for pseudorandom number generation	PROC CQLIM	SEED=
Bayesian Markov Chain Monte Carlo (MCMC) Options		
Specifies the number of burn-in iterations	BAYES	NBURNIN=
Specifies the number of Markov chains to run during the sampling phase	BAYES	NCHAIN=
Specifies the number of iterations to run during the sampling phase	BAYES	NSAMPLE=
Specifies the MCMC sampler and its options	BAYES	SAMPLER=
Specifies the random number generator seed	BAYES	SEED=
Controls the thinning of the Markov chain	BAYES	THIN=
Bayesian Output Tables		
Displays MCMC diagnostics	BAYES	DIAGNOSTICS=
Displays MCMC diagnostics for each Markov chain	BAYES	DIAGNOSTICS(BYCHAIN)=
Displays the settings used for all MCMC diagnostics	BAYES	DIAGNOSTICS(SETTINGS)=
Displays a summary of all parameters and their priors	BAYES	PRIORSUMMARY
Displays the settings used for the MCMC sampler	BAYES	SAMPLERSETTINGS
Displays a summary of the MCMC sampler used	BAYES	SAMPLERSUMMARY
Displays posterior summary statistics	BAYES	STATISTICS=
Displays posterior summary statistics for each Markov chain	BAYES	STATISTICS(BYCHAIN)=

Table 12.1 *continued*

Description	Statement	Option
Bayesian Posterior Sample		
Specifies options for saving a SAS data table for the posterior sample	BAYES	OUTPOST=
Bayesian Prior Options		
Specifies the Cauchy prior distribution	PRIOR	CAUCHY()
Specifies the gamma prior distribution	PRIOR	GAMMA()
Specifies the inverse gamma prior distribution	PRIOR	IGAMMA()
Specifies the normal prior distribution	PRIOR	NORMAL()
Specifies the square root gamma prior distribution	PRIOR	SQRTGAMMA()
Specifies the square root inverse gamma prior distribution	PRIOR	SQRTIGAMMA()
Specifies the <i>t</i> prior distribution	PRIOR	T()
Specifies the uniform prior distribution	PRIOR	UNIFORM()
Endogenous Variable Options		
Specifies a discrete variable	ENDOGENOUS	DISCRETE()
Specifies a censored variable	ENDOGENOUS	CENSORED()
Specifies a truncated variable	ENDOGENOUS	TRUNCATED()
Specifies a stochastic frontier variable	ENDOGENOUS	FRONTIER()
Heteroscedasticity Model Options		
Specifies the function for heteroscedasticity models	HETERO	LINK=
Squares the function for heteroscedasticity models	HETERO	SQUARE
Specifies no constant for heteroscedasticity models	HETERO	NOCONST
Output Control Options		
Specifies the ODS tables to display	DISPLAY	
Specifies the ODS tables to save as output tables	DISPLAYOUT	
Outputs the predicted values	OUTPUT	PREDICTED
Outputs the structured part	OUTPUT	XBETA
Outputs the residuals	OUTPUT	RESIDUAL
Outputs the error standard deviation	OUTPUT	ERRSTD
Outputs the marginal effects	OUTPUT	MARGINAL
Outputs the probability for the current response	OUTPUT	PROB
Outputs the probability for all responses	OUTPUT	PROBALL
Outputs the expected value	OUTPUT	EXPECTED
Outputs the conditional expected value	OUTPUT	CONDITIONAL
Outputs the inverse Mills ratio	OUTPUT	MILLS
Outputs the technical efficiency measures	OUTPUT	TE1
	OUTPUT	TE2

Table 12.1 *continued*

Description	Statement	Option
Test Request Options		
Requests Wald, Lagrange multiplier, and likelihood ratio tests	TEST	ALL
Requests the Wald test	TEST	WALD
Requests the Lagrange multiplier test	TEST	LM
Requests the likelihood ratio test	TEST	LR

PROC CQLIM Statement

PROC CQLIM < *options* > ;

The PROC CQLIM statement invokes the CQLIM procedure. You can specify the following *options*.

Data Table Options

DATA=*libref.data-table*

names the input data table for PROC CQLIM to use. The default is the most recently created data table. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 562.

data-table specifies the name of the input data table.

Printing Options

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

ITPRINT

prints the initial parameter estimates, convergence criteria, and all constraints of the optimization. At each iteration, the objective function value, step size, maximum gradient, and slope of search direction are also printed.

Model Estimation Options

COVEST=HESSIAN | OP | QML

specifies the method to use for calculating the covariance matrix of parameter estimates. You can specify the following covariance options:

HESSIAN	specifies the covariance from the inverse Hessian matrix.
OP	specifies the covariance from the outer product matrix.
QML	specifies the covariance from the outer product and Hessian matrices (the quasi-maximum likelihood estimates).

By default, COVEST=HESSIAN.

NDRAW=*value*

specifies the number of draws for Monte Carlo integration.

SEED=*value*

specifies a seed for pseudorandom number generation in Monte Carlo integration.

Optimization Control Options

PROC CQLIM uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can specify the following *options*:

MAXITER=*i*

MAXIT=*i*

specifies the maximum number of iterations in the optimization process. By default, MAXITER=200.

METHOD=CONGRA | DBLDOG | NEWRAP | NONE | NRRIDG | QUANEW | TRUREG

specifies the iterative minimization method to use. You can specify the following methods:

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
NEWRAP	specifies the Newton-Raphson method.
NONE	specifies that no optimization be performed beyond using the ordinary least squares method to compute the parameter estimates.
NRRIDG	specifies the Newton-Raphson ridge method.
QUANEW	specifies the quasi-Newton method.
TRUREG	specifies the trust region method.

By default, METHOD=NEWRAP.

BAYES Statement

BAYES < options > ;

The BAYES statement controls the Markov chain Monte Carlo sampling scheme that is used to obtain a sample from the posterior distribution, as well as the Bayesian output tables, including diagnostics and statistics. The BAYES statement is incompatible with multiple MODEL statements; with the BOUNDS, HETERO, RESTRICT, and TEST statements; with stochastic frontier models; and with ordinal models. You can specify the following *options*:

DIAGNOSTICS < (diag-options) >=ALL | NONE | keyword-list | (keyword-list)

DIAG < (diag-options) >=ALL | NONE | keyword-list | (keyword-list)

specifies which diagnostics to produce. If the value of the NCHAIN= option is greater than 1, then instead of the diagnostic tables being produced for each Markov chain, by default the results of the diagnostics for all the chains are appropriately combined and summarized. For more information, see the section “[Using Multiple Chains](#)” on page 37 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or both of the following *diag-options*:

BYCHAIN

produces diagnostic tables for each Markov chain. If NCHAIN=1, then the BYCHAIN option does nothing.

SETTINGS

produces a table of all MCMC diagnostic settings.

If you specify both the BYCHAIN and SETTINGS options, separate them by using a space or a comma. To produce all diagnostics, specify DIAGNOSTICS=ALL. To produce no diagnostics, specify DIAGNOSTICS=NONE. To produce some but not all diagnostics, or to change certain settings of these diagnostics, specify one or more of the following keywords. If you specify multiple keywords, separate them by using spaces.

AUTOCORR < (LAGS=numeric-list) >

AC < (LAGS=numeric-list) >

computes the autocorrelations at lags that you specify in the *numeric-list*. For more information, see the section “[Autocorrelations](#)” on page 34 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” Elements in the *numeric-list* must be positive integers, and values can be separated either by spaces or by commas. Repeated values are removed. If you omit the LAGS= option, autocorrelations of lags 1, 5, 10, and 50 are computed.

GEWEKE < (geweke-options) >

GEW < (geweke-options) >

computes the Geweke spectral density diagnostics. For more information, see the section “[Geweke Diagnostics](#)” on page 28 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *geweke-options*:

ALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the Geweke test. By default, ALPHA=0.05.

FRAC1=*value*

F1=*value*

specifies the fraction f_1 for the first window. By default, FRAC1=0.1.

FRAC2=*value*

F2=*value*

specifies the fraction f_2 for the second window. By default, FRAC2=0.5.

HEIDELBERGER <(heidel-options)>

HEIDEL <(heidel-options)>

HB <(heidel-options)>

computes the Heidelberg-Welch diagnostic for each variable. For more information, see the section “[Heidelberg-Welch Diagnostics](#)” on page 30 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or more of the following *heidel-options*:

EPSILON=*value*

EPS=*value*

specifies a positive number ϵ such that if the halfwidth is less than ϵ times the sample mean of the retained iterates, the halfwidth test is passed. By default, EPSILON=0.1.

HALFWIDTH_ALPHA=*value*

HALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the halfwidth test. By default, HALFWIDTH_ALPHA=0.05.

STATIONARY_ALPHA=*value*

SALPHA=*value*

specifies the α level ($0 < \alpha < 1$) for the stationarity test. By default, STATIONARY_ALPHA=0.05.

RAFTERY <(raftery-options)>

RL <(raftery-options)>

computes the Raftery-Lewis diagnostics. For more information, see the section “[Raftery-Lewis Diagnostics](#)” on page 31 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify one or more of the following *raftery-options*:

ACCURACY=*value*

ACC=*value*

R=*value*

specifies a small positive number r as the margin of error for measuring the accuracy of estimation of the quantile. By default, ACCURACY=0.005.

EPSILON=*value*

EPS=*value*

specifies the tolerance level (ϵ , a small positive number) for the stationary test. By default, EPSILON=0.001.

PROBABILITY=*value*

PROB=*value*

S=*value*

specifies the probability s of attaining the accuracy of the estimation of the quantile. By default, PROBABILITY=0.95.

QUANTILE=*value*

QUANT=*value*

Q=*value*

specifies the order (q , a value between 0 and 1) of the quantile of interest. By default, QUANTILE=0.025.

SUMMARIES <(MAXLAG=*value*)>

SUMMARY <(MAXLAG=*value*)>

SUM <(MAXLAG=*value*)>

computes a summary of MCMC diagnostics for each parameter in the Markov chain, including effective sample size (ESS), Monte Carlo standard error (MCSE), and related diagnostics. For more information about ESS, see the section “[Effective Sample Size](#)” on page 34 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#)”; for more information about MCSE, see the section “[Standard Error of the Mean Estimate](#)” on page 36 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” MAXLAG=*value* specifies the maximum autocorrelation lag to use for computing ESS, which is used to compute MCSE, where *value* must be a positive integer. By default, MAXLAG=250.

By default, DIAGNOSTICS=SUMMARIES.

DISTRIBUTED

DISTRIBUTE

keeps the data in the input table distributed on the CAS server when the server runs in massively parallel processing (MPP) mode. If you omit this option, instead the data are copied onto each worker for Bayesian inference, and multiple Markov chains are run in parallel. This option is ignored when the CAS server runs in symmetric multiprocessing (SMP) mode. For more information, see the section “[Distributed Data and MCMC](#)” on page 607.

NBURNIN=*number*

BURNIN=*number*

NBI=*number*

specifies the number of burn-in iterations to perform in each Markov chain before the chains are saved. For more information, see the section “[Burn-In, Thinning, and Markov Chain Samples](#)” on page 27 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, NBURNIN=0.

NCHAIN=*number*

NCHAINS=*number*

CHAINS=*number*

specifies the number of Markov chains to run. By default, NCHAIN=1.

NSAMPLE=*number*

NSAM=*number*

NMC=*number*

specifies the number of iterations after tuning and burn-in to save in each Markov chain. For more information, see the section “[Burn-In, Thinning, and Markov Chain Samples](#)” on page 27 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, NSAMPLE=1000.

OUTPOST<(*outpost-option*)>=*libref.data-table*

names the SAS data table to contain the posterior sample. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the output data table. For more information about this two-level name, see the [DATA=](#) option and the section “[Using CAS Sessions and CAS Engine Librefs](#)” on page 562. You can specify the following *outpost-option*:

DETAILED

saves any relevant additional variables, such as auxiliary variables, in the SAS data table. The random walk Metropolis (RWM) sampler without the [TRANSFORM](#) option has no additional variables to save. With the TRANSFORM option, the SAS data table also includes the transformed version of each parameter and the log posterior of the transformed parameters. When you use the No-U-Turn Sampler (NUTS) by specifying the [SAMPLER=NUTS](#) option, the SAS data table includes those additional variables, as well as the tree height that is achieved at every iteration.

WARMUP

saves warmup (tuning and burn-in) iterations in the SAS data table. This option is not available for the random walk Metropolis (RWM) sampler.

PRIORSUMMARY <(*priorsum-option*)>

PRIORSUM <(*priorsum-option*)>

produces a summary of all parameters in the model and their prior distributions. You can specify the following *priorsum-option*:

SHOWNAMES

NAMES

adds a column that displays the names of all parameters in the model. These are the names that you use to specify prior distributions on those parameters.

SAMPLER=NUTS <(*nuts-options*)> | **RWM** <(*rwm-options*)>

SAMPLING=NUTS <(*nuts-options*)> | **RWM** <(*rwm-options*)>

specifies how to sample from the posterior distribution. By default, SAMPLER=RWM.

NUTS <(nuts-options)>

samples from the posterior distribution by using the No-U-Turn Sampler. You can specify the following *nuts-options*:

DELTA=*number*

TARGETRATE=*number*

RATE=*number*

specifies the target Metropolis acceptance rate δ for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, DELTA=0.8.

MASSTUNE=NONE | WINDOWED <(windowed-options)>

specifies the mass matrix tuning method for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, MASSTUNE=WINDOWED. You can specify the following values:

NONE

specifies no mass matrix tuning. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607.

WINDOWED <(windowed-options)>**WINDOW** <(windowed-options)>**WIN** <(windowed-options)>

specifies the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. You can specify the following *windowed-options*:

EXPANDRATE=*number*

EXPRATE=*number*

RATE=*number*

specifies the window expansion rate γ for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, EXPANDRATE=2.

FINALWINDOW=*number*

FINAL=*number*

specifies the size of the final tuning window n_K for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, FINALWINDOW=50.

INITWINDOW=*number*

INIT=*number*

specifies the size of the initial tuning window n_1 for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, INITWINDOW=75.

MIDWINDOW=number

MID=number

specifies the size of the first middle tuning window n_2 for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, MIDWINDOW=25.

OVERLAPPING

OVERLAP

OVER

uses overlapping windows for the windowed mass matrix tuning method. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607.

MAXHEIGHT=number

MAXDEPTH=number

MAXTREE=number

specifies the maximum height of the binary tree $J_{\max}$ for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. To see how many times the algorithm reaches the maximum tree height during sampling, use the [SAMPLERSUMMARY](#) option. By default, MAXHEIGHT=10.

MAXHEIGHTKILL= k | INFINITY

MAXDEPTHKILL= k | INFINITY

MAXTREEKILL= k | INFINITY

specifies the maximum number of times the No-U-Turn Sampler can reach the maximum binary tree height before the simulation stops. To see how many times the algorithm reaches the maximum tree height during sampling, use the [SAMPLERSUMMARY](#) option. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. You can specify the following values:

k

specifies the maximum number of times. If $k=0$, then there is no maximum.

INFINITY

INFTY

INF

specifies no maximum number of times.

By default, MAXHEIGHTKILL=0.

NTUNE=number

NTU=number

specifies the number of iterations n_{tune} for the No-U-Turn Sampler. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607. By default, NTUNE=2000.

RWM <(rwm-options)>

samples from the posterior distribution by using the random walk Metropolis scheme. You can specify the following *rwm-options*:

ACCTOL=*value*

ATOL=*value*

specifies the tolerance ϵ for the acceptance rate during the tuning process of the random walk Metropolis (RWM) sampler. For more information, see the section “[Scale Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, ACCTOL=0.075.

INITSCALE=*value*

SCALE=*value*

specifies the initial scale parameter(s) c^{cur} of the RWM proposal distribution. For more information, see the section “[Scale Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, INITSCALE=2.38.

NTUNE=*number*

NTU=*number*

specifies the number of iterations n_{tune} for each tuning stage of the random walk Metropolis sampler. For more information, see the section “[Tuning the Random Walk Metropolis Sampler](#)” on page 606. By default, NTUNE=500.

NTUNESTAGE=*number*

specifies the number of tuning stages n_{stage} . For more information, see the section “[Tuning the Random Walk Metropolis Sampler](#)” on page 606. By default, NTUNESTAGE=24.

TARGETRATE=*value*

RATE=*value*

DELTA=*value*

specifies the target acceptance rate δ of the random walk Metropolis sampler. For more information, see the section “[Tuning Random Walk Metropolis Algorithms](#)” on page 19 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, TARGETRATE=0.234.

TRANSFORM

TRANS

transforms all parameters to an unconstrained space and implements the random walk Metropolis sampler on the unconstrained space. For more information, see the section “[Parameter Transformation](#)” on page 25 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

TUNEWEIGHT=*value*

WEIGHT=*value*

WT=*value*

specifies the tuning weight w to use during the tuning phase of the random walk Metropolis sampler to tune the proposal covariance matrix. For more information, see the section “[Covariance Tuning](#)” on page 20 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” By default, TUNEWEIGHT=0.75.

SAMPLERSETTINGS**SAMSETTINGS****SAMSET**

produces a summary of the MCMC sampler settings that are used to sample from the posterior distribution, including tuning settings.

SAMPLERSUMMARY<(VERBOSE)>**SAMSUMMARY<(VERBOSE)>****SAMSUM<(VERBOSE)>**

produces a summary of the MCMC sampler that is used to sample from the posterior distribution. For the RWM sampler, this option produces a table of the Metropolis acceptance rates. For NUTS, this option produces a table of the Metropolis acceptance rates as well as a table of NUTS diagnostics. You can specify the following suboption:

VERBOSE

produces a more detailed summary of the MCMC sampler. For the RWM sampler, this option does nothing. For NUTS, this option produces a table of the final mass matrix that is used after tuning. For more information, see the section “[Tuning the No-U-Turn Sampler](#)” on page 607.

SEED=number

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator in the simulation. Specifying a seed enables you to reproduce identical Markov chains for the same specification. If you do not specify this option, or if you specify a nonpositive seed, a random seed is generated by reading the time of day from the computer’s clock.

STATISTICS<(stat-option)>=ALL | NONE | keyword | (keyword-list)**STATISTIC<(stat-option)>=ALL | NONE | keyword | (keyword-list)****STATS<(stat-option)>=ALL | NONE | keyword | (keyword-list)****STAT<(stat-option)>=ALL | NONE | keyword | (keyword-list)**

specifies which posterior summary statistics to produce. If the value of the NCHAIN= option is greater than 1, then instead of the posterior summary statistics being computed separately for each Markov chain, by default the posterior summary statistics are computed by using all chains. For more information, see the section “[Using Multiple Chains](#)” on page 37 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *stat-option*:

BYCHAIN

produces posterior summary statistics tables for each Markov chain. If NCHAIN=1, then the BYCHAIN option does nothing.

To produce all statistics, specify STATISTICS=ALL. To produce no statistics, specify STATISTICS=NONE. To produce some but not all statistics, or to change certain settings of these statistics, specify one or more of the following keywords. If you specify multiple keywords, separate them by using spaces.

CORR**COR**

produces the posterior correlation matrix.

COV

produces the posterior covariance matrix.

INTERVAL < (*interval-option*) >**INTERVALS** < (*interval-option*) >**INT** < (*interval-option*) >

produces equal-tail posterior credible intervals and highest posterior density (HPD) credible intervals. For more information, see the sections “[Interval Estimation](#)” on page 10 and “[Summary Statistics](#)” on page 35 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *interval-option*:

ALPHA=*numeric-list*

ALPHAS=*numeric-list*

computes posterior credible intervals at the levels that you specify in the *numeric-list*. Elements in the *numeric-list* must be between 0 and 1, and values can be separated either by spaces or by commas. Repeated values are removed. Each value in the *numeric-list* produces a pair of 100(1-*value*)% equal-tail and HPD intervals for each parameter. By default, ALPHA=0.05, which yields the 95% credible intervals for each parameter.

SUMMARIES < (*summary-option*) >**SUMMARY** < (*summary-option*) >**SUM** < (*summary-option*) >

produces the means, standard deviations, and percentiles for the posterior sample. For more information, see the section “[Summary Statistics](#)” on page 35 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” You can specify the following *summary-option*:

PERCENTILES=*numeric-list*

PERCENTILE=*numeric-list*

PERCENT=*numeric-list*

PERC=*numeric-list*

PCT=*numeric-list*

computes the percentiles of the posterior sample that you specify in the *numeric-list*. Elements in the *numeric-list* must be between 0 and 100, and values can be separated either by spaces or by commas. Repeated values are removed. By default, PERCENTILES=(2.5 25 50 75 97.5), which yields the 2.5th, 25th, 50th, 75th, and 97.5th percentiles, respectively, for each parameter.

By default, STATISTICS=SUMMARIES.

THIN=*k*

THINNING=*k*

thins the Markov chain by using only one of every *k* iterations. For more information, see the section “Burn-In, Thinning, and Markov Chain Samples” on page 27 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” By default, THIN=1.

BOUNDS Statement

BOUNDS *bound1* < , *bound2* ... > ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. BOUNDS statement constraints refer to the parameters that are estimated by the CQLIM procedure. You can specify any number of BOUNDS statements.

Each *bound* is composed of parameters, constants, and inequality operators. Parameters that are associated with regressor variables are referred to by the names of the corresponding regressor variables. Specify each bound as follows:

item operator item < *operator item* < *operator item* ... > >

Each *item* is a constant, the name of a parameter, or a list of parameter names. For more information about how parameters are named in the CQLIM procedure, see the section “Naming of Parameters” on page 614. Each *operator* is <, >, <=, or >=.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints; however, the BOUNDS statement provides a simpler syntax for specifying these types of constraints. For more information, see the section “RESTRICT Statement” on page 596.

The following BOUNDS statement constrains the estimates of the parameters that are associated with the variable *ttime* and the variables *x1* through *x10* to be between 0 and 1. The following example illustrates the use of parameter lists to specify boundary constraints:

```
bounds 0 < ttime x1-x10 < 1;
```

The following BOUNDS statement constrains the estimates of the correlation (_RHO) and sigma (_SIGMA) in the bivariate model:

```
bounds _rho >= 0, _sigma.y1 > 1, _sigma.y2 < 5;
```

The BOUNDS statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

BY Statement

BY *variables* ;

A BY statement can be used in PROC CQLIM to obtain separate analyses of observations in groups defined by the BY variables.

CLASS Statement

CLASS *variable* <(options)>...<*variable* <(options)>> </global-options> ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You are not required to list the response variable for discrete choice models in the CLASS statement. Table 12.2 summarizes the values that you can use for either an *option* or a *global-option*. By default, REF=LAST. The options are fully documented in the section “CLASS Statement” on page 56 in Chapter 4, “Shared Concepts.”

Table 12.2 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable

DISPLAY Statement

DISPLAY <*table-list*> </options> ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[ODS Table Names](#)” on page 615. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see [SAS Output Delivery System: Procedures Guide](#).

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

<i>key=value</i>	specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name.
<i>key</i>	specifies <i>key</i> as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 615. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

ENDOGENOUS Statement

ENDOGENOUS *variables* ~ *options* ;

The ENDOGENOUS statement specifies the type of dependent variables that appear on the left-hand side of the equation. Endogenous variables listed refer to the dependent variables that appear on the left-hand side of the equation. You can specify the following options.

Discrete Variable Options

DISCRETE < (*discrete-options*) >

specifies that the endogenous variables in this statement be discrete. The BAYES statement is not compatible with ordinal models—that is, discrete models that have more than two levels of the endogenous variable. You can specify the following *discrete-options*:

DISTRIBUTION=LOGISTIC | NORMAL

DIST=LOGISTIC | NORMAL

D=LOGISTIC | NORMAL

specifies the cumulative distribution function to use to model the response probabilities. You can specify the following distribution types:

LOGISTIC specifies the logistic distribution for the logit model.

NORMAL specifies the normal distribution for the probit model.

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

ORDER=FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the discrete variables that you specify in the ENDOGENOUS statement. This sort order determines which parameters in the model correspond to each level in the data. You can specify the following sort orders:

DATA	sorts levels by order of appearance in the input data table.
FORMATTED	sorts levels by formatted value. The sort order is machine-dependent.
FREQ	sorts levels by descending frequency count; levels that have the most observations come first in the order.
INTERNAL	sorts levels by unformatted value. The sort order is machine-dependent.

By default, ORDER=FORMATTED. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

Censored Variable Options

CENSORED (*censored-options*)

censors the endogenous variables in this statement. You can specify the following *censored-options*:

LB=*value* | *variable*

LOWERBOUND=*value* | *variable*

specifies the lower bound of the censored variables. If *value* is missing or the value of *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value* | *variable*

UPPERBOUND=*value* | *variable*

specifies the upper bound of the censored variables. If *value* is missing or the value of *variable* is missing, no upper bound is set. By default, no upper bound is set.

Truncated Variable Options

TRUNCATED (*truncated-options*)

truncates the endogenous variables in the statement. You can specify the following *truncated-options*:

LB=*value* | *variable*

LOWERBOUND=*value* | *variable*

specifies the lower bound of the truncated variables. If *value* is missing or the value of *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value* | *variable*

UPPERBOUND=*value* | *variable*

specifies the upper bound of the truncated variables. If *value* is missing or the value of *variable* is missing, no upper bound is set. By default, no upper bound is set.

Stochastic Frontier Variable Options

FRONTIER <(*frontier-options*)>

specifies a stochastic frontier model. You can specify the following *frontier-options*:

COST

specifies that the estimated model be a cost function.

PRODUCTION

specifies that the estimated model be a production function.

TYPE=EXPONENTIAL | HALF | TRUNCATED

specifies the model type. You can specify the following types:

EXPONENTIAL specifies an exponential model.

HALF specifies a half-normal model.

TRUNCATED specifies a truncated normal model.

If neither PRODUCTION nor COST is specified, a production function is estimated by default. The BAYES statement is not compatible with stochastic frontier models.

FREQ Statement

FREQ *variable* ;

The FREQ statement identifies a variable that contains the frequency of occurrence of each observation. PROC CQLIM treats each observation as if it appeared n times, where n is the value of the FREQ variable for the observation. If the frequency value is not an integer, it is truncated to an integer. If the frequency value is less than 1 or missing, the observation is not used in the model fitting. When the FREQ statement is not specified, each observation is assigned a frequency of 1. If you specify more than one FREQ statement, then only the first FREQ statement is used.

HETERO Statement

HETERO *dependent-variables* ~ *exogenous-variables* </ options > ;

The HETERO statement specifies variables that are related to the heteroscedasticity of the residuals and the way that these variables are used to model the error variance. PROC CQLIM supports the following heteroscedastic regression model:

$$y_i = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$\epsilon_i \sim N(0, \sigma_i^2)$$

For more information about the specification of functional forms, see the section “[Heteroscedasticity](#)” on page 602.

The HETERO statement is currently not supported with a BAYES statement.

You can use the HETERO statement only for univariate models.

The following *options* specify the functional forms of heteroscedasticity:

LINK=EXP | LINEAR

specifies the functional form. You can specify the following values:

EXP specifies the exponential link function:

$$\sigma_i^2 = \sigma^2(1 + \exp(\mathbf{z}_i' \boldsymbol{\gamma}))$$

LINEAR specifies the linear link function:

$$\sigma_i^2 = \sigma^2(1 + \mathbf{z}_i' \boldsymbol{\gamma})$$

By default, LINK=EXP.

NOCONST

specifies that no constant appear in the exponential heteroscedasticity model:

$$\sigma_i^2 = \sigma^2 \exp(\mathbf{z}_i' \boldsymbol{\gamma})$$

SQUARE

estimates the model by using the square of the linear heteroscedasticity function. For example, you can specify the heteroscedasticity function

$$\sigma_i^2 = \sigma^2(1 + (\mathbf{z}_i' \boldsymbol{\gamma})^2)$$

by using the following code:

```
model y = x1 x2 / censored(lb=0);
hetero y ~ z1 / link=linear square;
```

The SQUARE option does not apply to the exponential heteroscedasticity function, because the square of an exponential function of $\mathbf{z}_i' \boldsymbol{\gamma}$ is the same as the exponential of $2\mathbf{z}_i' \boldsymbol{\gamma}$. Hence, the only difference is that all $\boldsymbol{\gamma}$ estimates are divided by two.

This option is ignored if you do not specify the LINK= option.

INIT Statement

INIT *initvalue1* < , *initvalue2* ... > ;

The INIT statement sets initial values for parameters in the optimization. You can specify any number of INIT statements.

Each *initvalue* is written as a parameter or parameter list, followed by an optional equality operator (=), followed by a number:

parameter <=> *number*

MODEL Statement

MODEL *dependent-variables* < (*order-options*) > = *regressors* < / *options* > ;

The MODEL statement specifies the dependent variable and independent regressor variables for the regression model.

You can specify the following *option* after a slash (/):

NOINT

suppresses the intercept parameter.

You can also specify the following endogenous variable options, which are the same as the options in the ENDOGENOUS statement. If you specify an endogenous variable option in both the MODEL statement and the ENDOGENOUS statement, only the option in the ENDOGENOUS statement is used.

Discrete Variable Options

DISCRETE < (*discrete-options*) >

specifies that the endogenous variables in the MODEL statement be discrete. The BAYES statement is not compatible with ordinal models—that is, discrete models that have more than two levels of the response variable. You can specify the following *discrete-options*:

DISTRIBUTION=LOGISTIC | NORMAL

DIST=LOGISTIC | NORMAL

D=LOGISTIC | NORMAL

specifies the cumulative distribution function to use to model the response probabilities. You can specify the following distribution types:

LOGISTIC specifies the logistic distribution for the logit model.

NORMAL specifies the normal distribution for the probit model.

By default, DISTRIBUTION=NORMAL.

If a multivariate model is specified, logistic distribution is not allowed. Only normal distribution is supported.

ORDER=FORMATTED | FREQ | INTERNAL

specifies the sort order for the levels of the discrete variables that you specify in the ENDOGENOUS statement. The sort order determines which parameters in the model correspond to each level in the data. You can specify the following sort orders:

FORMATTED sorts levels by formatted value. The sort order is machine-dependent.

FREQ sorts levels by descending frequency count; levels that have the most observations come first in the order.

INTERNAL sorts levels by unformatted value. The sort order is machine-dependent.

By default, ORDER=FORMATTED. For more information about sort order, see the chapter on the SORT procedure in the *Base SAS Procedures Guide*.

Censored Variable Options

CENSORED <(censored-options)>

censors the endogenous variables in this statement. You can specify the following *censored-options*:

LB=*value* | *variable*

LOWERBOUND=*value* | *variable*

specifies the lower bound of the censored variables. If *value* is missing or the value of *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value* | *variable*

UPPERBOUND=*value* | *variable*

specifies the upper bound of the censored variables. If *value* is missing or the value of *variable* is missing, no upper bound is set. By default, no upper bound is set.

Truncated Variable Options

TRUNCATED <(truncated-options)>

truncates the endogenous variables in this statement. You can specify the following *truncated-options*:

LB=*value* | *variable*

LOWERBOUND=*value* | *variable*

specifies the lower bound of the truncated variables. If *value* is missing or the value of *variable* is missing, no lower bound is set. By default, no lower bound is set.

UB=*value* | *variable*

UPPERBOUND=*value* | *variable*

specifies the upper bound of the truncated variables. If *value* is missing or the value of *variable* is missing, no upper bound is set. By default, no upper bound is set.

Stochastic Frontier Variable Options

FRONTIER <(frontier-options)>

specifies the stochastic frontier model. You can specify the following *frontier-options*:

COST

specifies that the estimated model be a cost function.

PRODUCTION

specifies that the estimated model be a production function.

TYPE=EXPONENTIAL | HALF | TRUNCATED

specifies the model type.

EXPONENTIAL specifies an exponential model.

HALF specifies a half-normal model.

TRUNCATED specifies a truncated normal model.

If neither PRODUCTION nor COST is specified, a production function is estimated by default. The BAYES statement is not compatible with stochastic frontier models.

OUTPUT Statement

OUTPUT **OUT=***libref.data-table* < *output-options* > ;

The OUTPUT statement creates a new SAS data table to contain variables that you specify using the COPYVAR option and the following quantities of interest if they are specified as *output-options*: estimates of $\mathbf{x}'\boldsymbol{\beta}$, predicted value, residual, marginal effects, probability, standard deviation of the error, expected value, conditional expected value, technical efficiency measures, and inverse Mills ratio. When the response values are missing for an observation, all output estimates except the residual for that observation are still computed as long as none of the explanatory variables are missing. This enables you to compute these statistics for prediction. You can specify only one OUTPUT statement.

You must specify the OUT= option:

OUT=*libref.data-table*

names the output data table for PROC CQLIM to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 562.

data-table specifies the name of the output data table.

You can specify one or more of the following *output-options*:

CONDITIONAL

outputs estimates of conditional expected values of continuous endogenous variables.

COPYVAR=*SAS-variable-names*

COPYVARS=(*SAS-variable-names*)

adds any SAS variables that appear in the input data table to the output data table.

ERRSTD

outputs estimates of σ_j , the standard deviation of the error term.

EXPECTED

outputs estimates of expected values of continuous endogenous variables.

MARGINAL

outputs marginal effects.

MILLS

outputs estimates of inverse Mills ratios of censored or truncated continuous variables and binary discrete variables.

PREDICTED

outputs estimates of predicted endogenous variables.

PROB

outputs estimates of probability of discrete endogenous variables that take the current observed responses.

PROBALL

outputs estimates of probability of discrete endogenous variables for all possible responses.

RESIDUAL

outputs estimates of residuals of continuous endogenous variables.

TE1

outputs estimates of technical efficiency for each producer in the stochastic frontier model that is suggested by Battese and Coelli (1988).

TE2

outputs estimates of technical efficiency for each producer in the stochastic frontier model that is suggested by Jondrow et al. (1982).

XBETA

outputs estimates of $\mathbf{x}'\boldsymbol{\beta}$.

PRIOR Statement

PRIOR *parameter-list* $\sim$ *distribution* ;

The PRIOR statement specifies the prior distribution of the model parameters for Bayesian analysis. You must specify a single parameter or a list of parameters, a tilde ($\sim$), and then a distribution with its parameters. You can specify multiple PRIOR statements, although PRIOR statements for parameters that do not exist in the model are ignored. For information about how parameters are named so that you can refer to them when specifying prior distributions, see the section “[Naming of Parameters](#)” on page 614. Alternatively, specifying the SHOWNAMES suboption of the [PRIORSUMMARY](#) option in the BAYES statement displays the names that are used for all parameters in the prior summary table.

You can specify the following *distributions*. All hyperparameters of the distribution must be specified, except LOWER and UPPER, which determine the support of the distribution and allow for truncated versions of many of them. For more information about these *distributions*, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” For more information about truncated prior distributions, see the section “[Truncated Prior Distributions](#)” on page 609.

CAUCHY(*cauchy-options*)

specifies independently and identically distributed [Cauchy distributions](#) for the *parameter-list*.

You must specify the following *cauchy-options*:

LOCATION= μ

LOC= μ

specifies the location parameter of the Cauchy distribution.

SCALE= γ

specifies the scale parameter of the Cauchy distribution, where $\gamma > 0$.

You can also specify the following *cauchy-options*:

LOWER= L | NEGATIVEINFINITY**LB= L | NEGATIVEINFINITY**

specifies the lower bound of the Cauchy distribution, where $L < U$. You can specify the following values:

L

uses L as the lower bound, such that the prior becomes a truncated Cauchy distribution.

NEGATIVEINFINITY**NEGINF****NEGINF**

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER= U | INFINITY**UB= U | INFINITY**

specifies the upper bound of the Cauchy distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated Cauchy distribution.

INFINITY**INF****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

GAMMA(*gamma-options*)

specifies independently and identically distributed [gamma distributions](#) for the *parameter-list*. You must specify the following *gamma-options*:

SCALE= b

specifies the scale parameter of the gamma distribution, where $b > 0$.

SHAPE= a

specifies the shape parameter of the gamma distribution, where $a > 0$.

You can also specify the following *gamma-options*:

LOWER=L**LB=L**

specifies the lower bound of the gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated gamma distribution.

By default, LOWER=0.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the gamma distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated gamma distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

IGAMMA(igamma-options)

specifies independently and identically distributed [inverse gamma distributions](#) for the *parameter-list*. You must specify the following *igamma-options*:

SCALE=b

specifies the scale parameter of the inverse gamma distribution, where $b > 0$.

SHAPE=a

specifies the shape parameter of the inverse gamma distribution, where $a > 0$.

You can also specify the following *igamma-options*:

LOWER=L**LB=L**

specifies the lower bound of the inverse gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated inverse gamma distribution.

By default, LOWER=0.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the inverse gamma distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated inverse gamma distribution.

INFINITY

INFTY

INF

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

NORMAL(*normal-options*)

specifies independently and identically distributed **normal distributions** for the *parameter-list*. You must specify the MEAN= *normal-option* and either the SD= or VAR= *normal-option*:

MEAN= μ

specifies the mean parameter of the normal distribution.

SD= σ

specifies the standard deviation parameter of the normal distribution, where $\sigma > 0$.

VAR= σ^2

specifies the variance parameter of the normal distribution, where $\sigma^2 > 0$.

You can also specify the following *normal-options*:

LOWER=*L* | **NEGATIVEINFINITY**

LB=*L* | **NEGATIVEINFINITY**

specifies the lower bound of the normal distribution, where $L < U$. You can specify the following values:

L

uses *L* as the lower bound, such that the prior becomes a truncated normal distribution.

NEGATIVEINFINITY

NEGINFTY

NEGINF

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER=*U* | **INFINITY**

UB=*U* | **INFINITY**

specifies the upper bound of the normal distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated normal distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

SQRTGAMMA(*sqrtgamma-options*)

specifies independently and identically distributed [square root gamma distributions](#) for the *parameter-list*. You must specify the following *sqrtgamma-options*:

SCALE=*b*

specifies the scale parameter of the square root gamma distribution, where $b > 0$.

SHAPE=*a*

specifies the shape parameter of the square root gamma distribution, where $a > 0$.

You can also specify the following *sqrtgamma-options*:

LOWER=*L***LB=*L***

specifies the lower bound of the square root gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated square root gamma distribution.

By default, LOWER=0.

UPPER=*U* | INFINITY**UB=*U* | INFINITY**

specifies the upper bound of the square root gamma distribution, where $U > L$. You can specify the following values:

U

uses *U* as the upper bound, such that the prior becomes a truncated square root gamma distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

SQRTIGAMMA(*sqrtigamma-options*)

specifies independently and identically distributed [square root inverse gamma distributions](#) for the *parameter-list*. You must specify the following *sqrtigamma-options*:

SCALE= b

specifies the scale parameter of the square root inverse gamma distribution, where $b > 0$.

SHAPE= a

specifies the shape parameter of the square root inverse gamma distribution, where $a > 0$.

You can also specify the following *sqrtigamma-options*:

LOWER= L **LB= L**

specifies the lower bound of the square root inverse gamma distribution, where $L \geq 0$ and $L < U$. If $L > 0$, the prior becomes a truncated square root inverse gamma distribution.

By default, LOWER=0.

UPPER= U | INFINITY**UB= U | INFINITY**

specifies the upper bound of the square root inverse gamma distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated square root inverse gamma distribution.

INFINITY

INFTY

INF

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

T(*t-options*)

specifies independently and identically distributed *t distributions* for the *parameter-list*.

You must specify the following *t-options*:

DF= ν

specifies the degrees-of-freedom parameter of the *t* distribution, where $\nu > 0$.

LOCATION= μ **LOC= μ**

specifies the location parameter of the *t* distribution.

SCALE= γ

specifies the scale parameter of the *t* distribution, where $\gamma > 0$.

You can also specify the following *t-options*:

LOWER=L | NEGATIVEINFINITY**LB=L | NEGATIVEINFINITY**

specifies the lower bound of the t distribution, where $L < U$. You can specify the following values:

L

uses L as the lower bound, such that the prior becomes a truncated t distribution.

NEGATIVEINFINITY**NEGINF****NEGINF**

uses negative infinity as the lower bound.

By default, LOWER=NEGATIVEINFINITY.

UPPER=U | INFINITY**UB=U | INFINITY**

specifies the upper bound of the t distribution, where $U > L$. You can specify the following values:

U

uses U as the upper bound, such that the prior becomes a truncated t distribution.

INFINITY**INFTY****INF**

uses positive infinity as the upper bound.

By default, UPPER=INFINITY.

UNIFORM(uniform-options)

specifies independently and identically distributed **uniform distributions** for the *parameter-list*. You must specify both the following *uniform-options*:

MAX=M | INFINITY

specifies the maximum value of the uniform distribution, where $M < m$. You can specify the following values:

M

uses M as the maximum value.

INFINITY**INFTY****INF**

uses positive infinity as the maximum value, such that the prior becomes an improper uniform prior.

MIN=*m* | NEGATIVEINFINITY

specifies the minimum value of the uniform distribution, where $m < M$. You can specify the following values:

m

uses *m* as the minimum value.

NEGATIVEINFINITY**NEGINFTY****NEGINF**

uses negative infinity as the minimum value, such that the prior becomes an improper uniform prior.

RESTRICT Statement

RESTRICT *restriction1* <, *restriction2* ... > ;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements, but the number of restrictions that are imposed is limited by the number of regressors.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=. The *operator* and second *expression* are optional.

Restriction expressions can be composed of parameter names; multiplication (*), addition (+), and subtraction (−) operators; and constants. Parameters that are named in restriction expressions must be among the parameters that are estimated by the model. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable. The restriction expressions must be a linear function of the parameters.

The following statements illustrate the use of the RESTRICT statement:

```
proc cqlim data=mylib.dataset;
  model y = x1-x10 / censored(lb=0);
  restrict x1*x2 <= x2 + x3;
run;
```

The RESTRICT statement can also be used to impose cross-equation restrictions in multivariate models. The following RESTRICT statement imposes an equality restriction on coefficients of *x1* in equation *y1* and *x1* in equation *y2*:

```
proc cqlim data=mylib.dataset;
  model y1 = x1-x10 / discrete;
  model y2 = x1-x4 / discrete;
  restrict y1.x1=y2.x1;
run;
```

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified by the names Restrict1, Restrict2, and so on. The test statistics and p -values for these restrictions are computed using the Lagrange multiplier test that is described in the section “Tests on Parameters” on page 604. Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

The RESTRICT statement is not supported if a BAYES statement is also specified. In Bayesian analysis, the restrictions on parameters are usually introduced through the prior distribution.

TEST Statement

`<label:> TEST <'string'> equation <, equation .../ options > ;`

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the regression parameters in the preceding MODEL statement. Each equation specifies a linear hypothesis to be tested. All hypotheses in one TEST statement are tested jointly. Variable names in the equations must correspond to regressors in the preceding MODEL statement, and each name represents the coefficient of the corresponding regressor. Use the keyword INTERCEPT for a test that includes a constant.

You cannot specify both the TEST statement and the BAYES statement.

You can specify the following *options* after the slash (/):

ALL

requests Wald, Lagrange multiplier, and likelihood ratio tests.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

WALD

requests the Wald test.

The following statements illustrate the use of the TEST statement (note the use of the INTERCEPT keyword in the second TEST statement):

```
proc cqlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0;
  test_int: test intercept = 0, x3 = 0;
run;
```

The first TEST statement investigates the joint hypothesis that

$$\beta_1 = 0$$

and

$$0.5\beta_2 + 2\beta_3 = 0$$

In case there is more than one MODEL statement in one CQLIM procedure, then TEST statement is capable of testing cross equation restrictions. Each parameter reference should be preceded by the name of the dependent variable of the particular model and the dot sign. For example,

```
proc cqlim;
  model y1 = x1 x2 x3;
  model y2 = x3 x5 x6;
  test y1.x1 + y2.x6 = 1;
run;
```

This cross equation test investigates the null hypothesis that

$$\beta_{1,1} + \beta_{2,3} = 1$$

in the system of equations

$$y_{1,i} = \alpha_1 + \beta_{1,1}x_{1,i} + \beta_{1,2}x_{2,i} + \beta_{1,3}x_{3,i}$$

$$y_{2,i} = \alpha_2 + \beta_{2,1}x_{3,i} + \beta_{2,2}x_{5,i} + \beta_{2,3}x_{6,i}$$

Only linear equality restrictions and tests are permitted in PROC CQLIM. Test expressions can be composed only of algebraic operations that involve the addition symbol (+), subtraction symbol (–), and multiplication symbol (*).

The TEST statement accepts labels that are reproduced in the printed output. You can label a TEST statement in two ways: you can specify a label followed by a colon before the TEST keyword, or you can specify a string in quotation marks after the TEST keyword. If you specify both a label before the TEST keyword and a quoted string after the keyword, PROC CQLIM uses the label that precedes the colon. If no label or quoted string is specified, PROC CQLIM labels the test automatically.

WEIGHT Statement

WEIGHT *variable* </option> ;

The WEIGHT statement specifies a variable that supplies weighting values to use for each observation in estimating parameters. The log likelihood for each observation is multiplied by the corresponding weight variable value.

If the weight of an observation is nonpositive, that observation is not used in the estimation.

You can add the following *option* after a slash (/):

NONNORMALIZE

specifies that the weights must be used as is. When you omit this option, the weights are normalized so that they add up to the actual sample size. Weights w_i are normalized by multiplying them by $\frac{n}{\sum_{i=1}^n w_i}$, where n is the sample size.

For more information about combining the WEIGHT statement with the [BAYES](#) statement, see the section “[Bayesian Analysis with Weighted Likelihoods](#)” on page 607.

Details: CQLIM Procedure

Ordinal Discrete Choice Modeling

Binary Probit and Logit Model

The binary choice model is

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where the value of the latent dependent variable, y_i^* , is observed only as follows:

$$\begin{aligned} y_i &= 1 && \text{if } y_i^* > 0 \\ &= 0 && \text{otherwise} \end{aligned}$$

The disturbance, ϵ_i , of the probit model has a standard normal distribution with the cumulative distribution function (CDF)

$$\Phi(x) = \int_{-\infty}^x \frac{1}{\sqrt{2\pi}} \exp(-t^2/2) dt$$

The disturbance of the logit model has a standard logistic distribution with the CDF

$$\Lambda(x) = \frac{\exp(x)}{1 + \exp(x)} = \frac{1}{1 + \exp(-x)}$$

The binary discrete choice model has the following probability that the event $\{y_i = 1\}$ occurs:

$$P(y_i = 1) = F(\mathbf{x}_i' \boldsymbol{\beta}) = \begin{cases} \Phi(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(probit)} \\ \Lambda(\mathbf{x}_i' \boldsymbol{\beta}) & \text{(logit)} \end{cases}$$

For more information, see *SAS/ETS User's Guide*.

Ordinal Probit/Logit

When the dependent variable is observed in sequence with M categories, binary discrete choice modeling is not appropriate for data analysis. McKelvey and Zavoina (1975) propose the ordinal (or ordered) probit model.

Consider the regression equation

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where error disturbances, ϵ_i , have the distribution function F . The unobserved continuous random variable, y_i^* , is identified as M categories. Suppose there are $M + 1$ real numbers, $\mu_0, \dots, \mu_M$, where $\mu_0 = -\infty$, $\mu_1 = 0$, $\mu_M = \infty$, and $\mu_0 \leq \mu_1 \leq \dots \leq \mu_M$. Define

$$R_{i,j} = \mu_j - \mathbf{x}_i' \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

For more information, see *SAS/ETS User's Guide*.

Limited Dependent Variable Models

Censored Regression Models

When the dependent variable is censored, all values within a certain range are transformed to a single value. For example, the standard Tobit model can be defined as

$$y_i^* = \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

$$y_i = \begin{cases} y_i^* & \text{if } y_i^* > 0 \\ 0 & \text{if } y_i^* \leq 0 \end{cases}$$

where $\epsilon_i \sim \text{iid}N(0, \sigma^2)$.

The Tobit model can be generalized to handle observation-by-observation censoring. The model that is censored on both the lower and upper limits can be defined as

$$y_i = \begin{cases} R_i & \text{if } y_i^* \geq R_i \\ y_i^* & \text{if } L_i < y_i^* < R_i \\ L_i & \text{if } y_i^* \leq L_i \end{cases}$$

For more information, see *SAS/ETS User's Guide*.

Truncated Regression Models

In a truncated model, the observed sample is a subset of the population in which the dependent variable falls within a certain range. For example, when neither a dependent variable nor exogenous variables are observed for $y_i^* \leq 0$, the truncated regression model can be specified as

$$\ell = \sum_{i \in \{y_i > 0\}} \left\{ -\ln \Phi(\mathbf{x}_i' \boldsymbol{\beta} / \sigma) + \ln \left[\frac{\phi((y_i - \mathbf{x}_i' \boldsymbol{\beta}) / \sigma)}{\sigma} \right] \right\}$$

For more information, see *SAS/ETS User's Guide*.

Stochastic Frontier Production and Cost Models

Stochastic frontier production models were first developed by Aigner, Lovell, and Schmidt (1977); Meeusen and van den Broeck (1977). Specification of these models allows for random shocks of the production or cost but also includes a term for technical or cost inefficiency. Assuming that the production function takes a log-linear Cobb-Douglas form, the stochastic frontier production model can be written as

$$\ln(y_i) = \beta_0 + \sum_n \beta_n \ln(x_{ni}) + \epsilon_i$$

where $\epsilon_i = v_i - u_i$. The v_i term represents the stochastic error component, and the u_i term represents the nonnegative, technical inefficiency error component. The v_i error component is assumed to be distributed iid normal and independent from u_i . If $u_i > 0$, the error term ϵ_i is negatively skewed and represents technical inefficiency. If $u_i < 0$, the error term ϵ_i is positively skewed and represents cost inefficiency. PROC CQLIM models the u_i error component as a half-normal, exponential, or truncated normal distribution.

The Normal-Half-Normal Model

When v_i is iid $N(0, \sigma_v^2)$ in a normal-half-normal model, u_i is iid $N^+(0, \sigma_u^2)$, with v_i and u_i independent of each other. Given the independence of error terms, the joint density of v and u can be written as

$$f(u, v) = \frac{2}{2\pi\sigma_u\sigma_v} \exp\left\{-\frac{u^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2}\right\}$$

Substituting $v = \epsilon + u$ into the preceding equation and integrating u out gives

$$f(\epsilon) = \frac{2}{\sigma} \phi\left(\frac{\epsilon}{\sigma}\right) \Phi\left(-\frac{\epsilon\lambda}{\sigma}\right)$$

where $\lambda = \sigma_u/\sigma_v$ and $\sigma = \sqrt{\sigma_u^2 + \sigma_v^2}$.

In the case of a stochastic frontier cost model, $v = \epsilon - u$ and

$$f(\epsilon) = \frac{2}{\sigma} \phi\left(\frac{\epsilon}{\sigma}\right) \Phi\left(\frac{\epsilon\lambda}{\sigma}\right)$$

For more information, see *SAS/ETS User's Guide*.

The Normal-Exponential Model

Under the normal-exponential model, v_i is iid $N(0, \sigma_v^2)$ and u_i is iid exponential. Given the independence of the error term components u_i and v_i , the joint density of v and u can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v} \exp\left\{-\frac{u}{\sigma_u} - \frac{v^2}{2\sigma_v^2}\right\}$$

The marginal density function of ϵ for the production function is

$$f(\epsilon) = \left(\frac{1}{\sigma_u}\right) \Phi\left(-\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u}\right) \exp\left\{\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2}\right\}$$

The marginal density function for the cost function is equal to

$$f(\epsilon) = \left(\frac{1}{\sigma_u}\right) \Phi\left(\frac{\epsilon}{\sigma_v} - \frac{\sigma_v}{\sigma_u}\right) \exp\left\{-\frac{\epsilon}{\sigma_u} + \frac{\sigma_v^2}{2\sigma_u^2}\right\}$$

For more information, see *SAS/ETS User's Guide*.

The Normal–Truncated Normal Model

The normal–truncated normal model is a generalization of the normal-half-normal model that allows the mean of u_i to differ from 0. Under the normal–truncated normal model, the error term component v_i is iid $N^+(0, \sigma_v^2)$, and the error term component u_i is iid $N(\mu, \sigma_u^2)$. The joint density of v_i and u_i can be written as

$$f(u, v) = \frac{1}{\sqrt{2\pi}\sigma_u\sigma_v\Phi(\mu/\sigma_u)} \exp\left\{-\frac{(u-\mu)^2}{2\sigma_u^2} - \frac{v^2}{2\sigma_v^2}\right\}$$

The marginal density function of ϵ for the production function is

$$f(\epsilon) = \frac{1}{\sigma}\phi\left(\frac{\epsilon + \mu}{\sigma}\right)\Phi\left(\frac{\mu}{\sigma\lambda} - \frac{\epsilon\lambda}{\sigma}\right)\left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1}$$

The marginal density function for the cost function is

$$f(\epsilon) = \frac{1}{\sigma}\phi\left(\frac{\epsilon - \mu}{\sigma}\right)\Phi\left(\frac{\mu}{\sigma\lambda} + \frac{\epsilon\lambda}{\sigma}\right)\left[\Phi\left(\frac{\mu}{\sigma_u}\right)\right]^{-1}$$

For more information, see *SAS/ETS User's Guide*.

For more information about normal-half-normal, normal-exponential, and normal–truncated normal models, see Kumbhakar and Lovell (2000); Coelli, Prasada Rao, and Battese (1998).

Heteroscedasticity

If the variance of regression disturbance ϵ_i is heteroscedastic, the variance can be specified as a function of variables

$$E(\epsilon_i^2) = \sigma_i^2 = f(\mathbf{z}_i'\boldsymbol{\gamma})$$

Table 12.3 shows various functional forms of heteroscedasticity and the corresponding options to request each model.

Table 12.3 Specification Summary for Modeling Heteroscedasticity

Number	Model	Options
1	$f(\mathbf{z}_i'\boldsymbol{\gamma}) = \sigma^2(1 + \exp(\mathbf{z}_i'\boldsymbol{\gamma}))$	LINK=EXP (default)
2	$f(\mathbf{z}_i'\boldsymbol{\gamma}) = \sigma^2 \exp(\mathbf{z}_i'\boldsymbol{\gamma})$	LINK=EXP NOCONST
3	$f(\mathbf{z}_i'\boldsymbol{\gamma}) = \sigma^2(1 + \sum_{l=1}^L \gamma_l z_{li})$	LINK=LINEAR
4	$f(\mathbf{z}_i'\boldsymbol{\gamma}) = \sigma^2(1 + (\sum_{l=1}^L \gamma_l z_{li})^2)$	LINK=LINEAR SQUARE

In model 3, variance of some observations might be negative. Although the CQLIM procedure assigns a large penalty to move the optimization away from such a region, the optimization might not be able to improve the objective function value and might become locked in the region. Signs of such an outcome include extremely small likelihood values or missing standard errors in the estimates. In model 2, variance is guaranteed to be greater than or equal to 0, but variances of some observations might be very close to 0. In these scenarios, standard errors might be missing. Models 1 and 4 do not have such problems. Variances in these models are always positive and never close to 0.

Bivariate Censored Dependent Variable Modeling

The generic form of a bivariate censored dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}'\boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}'\boldsymbol{\beta}_2 + \epsilon_{2i} \end{aligned}$$

where the disturbances, ϵ_{1i} and ϵ_{2i} , have a joint normal distribution with zero mean, standard deviations σ_1 and σ_2 , and correlation ρ . The variables y_1^* and y_2^* are latent variables. The dependent variables y_1 and y_2 might or might not be censored at the edges of the bivariate interval $\{[L_1, R_1], [L_2, R_2]\}$, depending on the behavior of the latent variables y_1^* and y_2^* :

$$y_{1i} = \begin{cases} R_1 & \text{if } R_1 < y_{1i}^* \\ y_{1i}^* & \text{if } L_1 \leq y_{1i}^* \leq R_1 \\ L_1 & \text{if } y_{1i}^* < L_1 \end{cases}$$

$$y_{2i} = \begin{cases} R_2 & \text{if } R_2 < y_{2i}^* \\ y_{2i}^* & \text{if } L_2 \leq y_{2i}^* \leq R_2 \\ L_2 & \text{if } y_{2i}^* < L_2 \end{cases}$$

There are three cases for the log likelihood of (y_{1i}, y_{2i}) . In the first case, $y_{1i} = y_{1i}^*$ and $y_{2i} = y_{2i}^*$. That is, both dependent variables are uncensored. The log likelihood is computed from a bivariate normal density,

$$\ell_i = \ln [\text{pdf}(y_{1i}^*, y_{2i}^*)] = \ln \left[\phi_2 \left(\frac{y_{1i} - \mathbf{x}_{1i}'\boldsymbol{\beta}_1}{\sigma_1}, \frac{y_{2i} - \mathbf{x}_{2i}'\boldsymbol{\beta}_2}{\sigma_2}, \rho \right) \right] - \ln \sigma_1 - \ln \sigma_2$$

where $\phi_2(u, v, \rho)$ is the probability density function (pdf) for a standardized bivariate normal distribution with correlation ρ ,

$$\phi_2(u, v, \rho) = \frac{e^{-(1/2)(u^2 + v^2 - 2\rho uv)/(1 - \rho^2)}}{2\pi(1 - \rho^2)^{1/2}}$$

In the second case, one dependent variable is censored and the other is not. For example, if $y_{1i} = y_{1i}^*$ and $y_{2i} = L_2$, then the log likelihood is computed as

$$\begin{aligned} \ell_i &= \ln \left[\int_{-\infty}^{L_2} \text{pdf}(y_{1i}^*, y_{2i}^*) dy_{2i}^* \right] = \ln \left[\int_{-\infty}^{L_2} \text{pdf}(y_{2i}^* | y_{1i}^*) \text{pdf}(y_{1i}^*) dy_{2i}^* \right] \\ &= \ln \left[\phi \left(\frac{y_{1i}^* - \mathbf{x}_{1i}'\boldsymbol{\beta}_1}{\sigma_1} \right) \right] - \ln \sigma_1 + \ln \left[\Phi \left(\frac{L_2 - \mathbf{x}_{2i}'\boldsymbol{\beta}_2 - \sigma_2 \rho \frac{y_{1i}^* - \mathbf{x}_{1i}'\boldsymbol{\beta}_1}{\sigma_1}}{\sigma_2 \sqrt{1 - \rho^2}} \right) \right] \end{aligned}$$

where ϕ and Φ are the probability density function and the cumulative probability function for a standardized univariate normal distribution, respectively.

In the third case, both dependent variables are censored. For example, if $y_{1i} = R_1$ and $y_{2i} = L_2$, then the log likelihood is

$$\ell_i = \ln \left[\int_{u=\frac{R_1 - \mathbf{x}_1' \boldsymbol{\beta}_1}{\sigma_1}}^{\infty} \int_{v=-\infty}^{\frac{L_2 - \mathbf{x}_2' \boldsymbol{\beta}_2}{\sigma_2}} \phi_2(u, v, \rho) du dv \right]$$

Multivariate Limited Dependent Models

Multivariate models are similar to bivariate models. The generic form of the multivariate limited dependent variable model is

$$\begin{aligned} y_{1i}^* &= \mathbf{x}_{1i}' \boldsymbol{\beta}_1 + \epsilon_{1i} \\ y_{2i}^* &= \mathbf{x}_{2i}' \boldsymbol{\beta}_2 + \epsilon_{2i} \\ &\vdots \\ y_{mi}^* &= \mathbf{x}_{mi}' \boldsymbol{\beta}_m + \epsilon_{mi} \end{aligned}$$

where m is the number of models to be estimated. The vector ϵ has a multivariate normal distribution with mean 0 and variance-covariance matrix Σ . As with bivariate models, calculating the likelihood can involve computing multivariate normal integrations. This is done using Monte Carlo integration. (See Genz 1992; Hajivassiliou and McFadden 1998.)

When the number of equations, N , increases in a system, the number of parameters increases at the rate of N^2 because of the correlation matrix. When the number of parameters is large, sometimes the optimization converges but some of the standard deviations are missing. This usually means that the model is overparameterized. The default method for computing the covariance is to use the inverse Hessian matrix. The Hessian is computed by finite differences, and in overparameterized cases, the inverse cannot be computed. It is recommended that you reduce the number of parameters in such cases. Sometimes it might also help to use the outer product covariance matrix (the COVEST=OP option in the PROC CQLIM statement).

Tests on Parameters

In general, you can write the tested hypothesis as

$$H_0 : \mathbf{h}(\theta) = 0$$

where $\mathbf{h}(\theta)$ is an $r \times 1$ vector-valued function of the parameters θ that is given by the r expressions that you specify in the TEST statement.

Let $\hat{V}$ be the estimate of the covariance matrix of $\hat{\theta}$. Let $\hat{\theta}$ be the unconstrained estimate of θ , and let $\tilde{\theta}$ be the constrained estimate of θ such that $\mathbf{h}(\tilde{\theta}) = 0$. Let

$$A(\theta) = \partial \mathbf{h}(\theta) / \partial \theta \big|_{\hat{\theta}}$$

Using this notation, you compute the test statistics for the three types of tests as follows:

- The Wald test statistic is defined as

$$W = h'(\hat{\theta}) \left(A(\hat{\theta}) \hat{V} A'(\hat{\theta}) \right)^{-1} h(\hat{\theta})$$

The Wald test is not invariant to reparameterization of the model (Gregory and Veall 1985; Gallant 1987, p. 219). For more information about the theoretical properties of the Wald test, see Phillips and Park (1988).

- The Lagrange multiplier test statistic is

$$LM = \lambda' A(\tilde{\theta}) \tilde{V} A'(\tilde{\theta}) \lambda$$

where λ is the vector of Lagrange multipliers from the computation of the restricted estimate $\tilde{\theta}$.

- The likelihood ratio test statistic is

$$LR = 2 \left(L(\hat{\theta}) - L(\tilde{\theta}) \right)$$

where $\tilde{\theta}$ represents the constrained estimate of θ and L is the concentrated log-likelihood value.

For each type of test, under the null hypothesis the test statistic is asymptotically distributed as a χ^2 random variable with r degrees of freedom, where r is the number of expressions in the TEST statement. The p -values that are reported for the tests are computed from the $\chi^2(r)$ distribution and are only asymptotically valid.

Monte Carlo simulations suggest that the asymptotic distribution of the Wald test is a poorer approximation of its small sample distribution than that of the other two tests. However, the Wald test has the lowest computational cost, because it does not require computation of the constrained estimate $\tilde{\theta}$.

The following statements use the TEST statement to perform a likelihood ratio test:

```
proc cqlim;
  model y = x1 x2 x3;
  test x1 = 0, x2 * .5 + 2 * x3 = 0 /lr;
run;
```

For more information, see [SAS/ETS User's Guide](#).

Bayesian Analysis

To perform Bayesian analysis, you must specify a BAYES statement. Unless otherwise stated, all options in this section are options in the BAYES statement.

Bayes' theorem states that the posterior density $\pi(\theta|y)$ can be obtained via

$$\pi(\theta|y) \propto \pi(\theta)L(y|\theta)$$

where θ is a parameter or a vector of parameters and $\pi(\theta)$ is the product of the prior densities that you specify in the PRIOR statement. The term $L(y|\theta)$ is the likelihood associated with the model that is implied by the MODEL statement. For an introduction to Bayesian analysis, see the section “Overview” on page 5 in Chapter 2, “Introduction to Bayesian Analysis Procedures.”

To perform Bayesian analysis, you must draw a random sample from the posterior density $\pi(\theta|y)$ by using the Markov chain Monte Carlo (MCMC) method. For an introduction to MCMC, see the section “Markov Chain Monte Carlo Method” on page 16 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” By default, PROC CQLIM uses the random walk Metropolis (RWM) algorithm to obtain the posterior sample. For an overview of Metropolis algorithms, see the section “Metropolis and Metropolis-Hastings Algorithms” on page 17 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” The RWM algorithm requires a proposal distribution to be tuned to match certain features of the posterior distribution. For more information about this tuning process, see the section “Tuning Random Walk Metropolis Algorithms” on page 19 in Chapter 2, “Introduction to Bayesian Analysis Procedures.”

Alternatively, PROC CQLIM can use the No-U-Turn Sampler (NUTS) algorithm, a variant of the Hamiltonian Monte Carlo (HMC) algorithm, to obtain the posterior sample. For an overview of HMC and NUTS, see the sections “Hamiltonian Monte Carlo Sampler” on page 21 and “No-U-Turn Sampler” on page 22 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” NUTS requires an integrator step size parameter and a mass matrix parameter to be tuned to match certain features of the posterior distribution. For more information about this tuning process, see the section “Tuning for NUTS” on page 23 in Chapter 2, “Introduction to Bayesian Analysis Procedures.”

Additional details specific to PROC CQLIM follow.

Tuning the Random Walk Metropolis Sampler

PROC CQLIM tunes the random walk Metropolis proposal distribution during a tuning phase that consists of n_{stage} tuning stages, each n_{tune} iterations long. For more information, see the section “Tuning Random Walk Metropolis Algorithms” on page 19 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” The random walk Metropolis proposal covariance matrix that is defined in that section, COV^{cur} , should approximate the posterior covariance matrix and must be initialized prior to tuning. PROC CQLIM always initializes it to the covariance matrix of the maximum likelihood estimates of the model parameters.

Tuning the No-U-Turn Sampler

PROC CQLIM tunes both the integrator step size and the mass matrix in a tuning phase that consists of n_{tune} iterations, divided into a sequence of tuning windows. For more information, see the section “[Tuning for NUTS](#)” on page 23 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” The step size is tuned throughout the entire tuning phase in order to achieve a desired Metropolis acceptance rate. The mass matrix is diagonal, and the ideal mass matrix is the diagonal matrix of inverse posterior variances. These posterior variances are learned in the tuning phase. PROC CQLIM always initializes the mass matrix to the diagonal matrix of the inverse square standard errors of the maximum likelihood parameter estimates.

Initial Values of the Markov Chain

PROC CQLIM starts each Markov chain at the maximum likelihood estimates (MLEs) of the parameters. If the MLE for a particular parameter is outside the support of its prior distribution, then PROC CQLIM instead initializes that parameter near the boundary of its prior support.

Bayesian Analysis with Weighted Likelihoods

In PROC CQLIM, you can account for sample weights in Bayesian analysis by using the [WEIGHT](#) statement, provided that the weights are handled properly. The weighted log-likelihood functions in PROC CQLIM have the form

$$\ell(\theta) = \sum_{i=1}^n w_i \ell_i(\theta)$$

where $\ell_i(\theta)$ is the log likelihood for observation i , w_i is the corresponding sample weight, and n is the sample size. When $w_i = 1$ for all i , this is equivalent to a nonweighted log likelihood. In this case the weights sum to the sample size.

In the general weighted case, the sum of the weights should still equal the sample size—that is, $\sum_{i=1}^n w_i = n$ —and w_i/n should represent the proportion of the sample size that corresponds to observation i . This ensures that the prior density and likelihood function are weighted correctly in the posterior density. For more information, see Savitsky and Toth (2016).

PROC CQLIM normalizes the weights to sum to the sample size by default, so weighted Bayesian analyses are valid. The [NONNORMALIZE](#) option in the [WEIGHT](#) statement tells PROC CQLIM not to normalize the weights, so it can result in misleading weighted Bayesian analyses and is generally not recommended.

The [FREQ](#) statement is similar to the [WEIGHT](#) statement, except that each frequency represents the sample size associated with the corresponding observation. By definition, the sum of the frequencies is equal to the sample size. So you can combine the [BAYES](#) statement with the [FREQ](#) statement without issue.

Distributed Data and MCMC

When you use a CAS server that is running in massively parallel processing (MPP) mode, the data are distributed across the workers of the server. Iterative methods such as MCMC can be significantly slower in this context because of communication costs. Additionally, when you request multiple Markov chains by using the [NCHAIN=](#) option, those chains are independent of each other and can be run in parallel instead of serially. When you perform Bayesian analysis by using the [BAYES](#) statement on a server in MPP mode, PROC CQLIM automatically tries to take advantage of the distributed environment to make MCMC run as fast as possible. To do this, it automatically copies the data onto each worker machine and divides the

number of requested Markov chains among the workers as evenly as possible. Then those workers run their chains in parallel and send their results back to the controller. MCMC is therefore always as slow as the slowest worker—typically one of the workers that have the most Markov chains if the chains cannot be evenly divided among the workers. The fastest possible CAS server configuration has at least as many workers as the number of Markov chains that you request, though there is no benefit to having more workers than chains.

Although copying the data to each of the workers and letting them run their own Markov chains in parallel is fast, it requires the data set to be small enough to fit on each worker machine. You can use the **DISTRIBUTED** option to instead keep the data distributed at the cost of a much slower analysis. The **DISTRIBUTED** option also enables you to obtain results that are numerically identical to those of PROC CQLIM in release 2021.2.3 and previous releases, which do not automatically copy the data set onto the workers for Bayesian analysis. If the CAS server is running in symmetric multiprocessing (SMP) mode, then the server has only a single machine and the **DISTRIBUTED** option does nothing.

Prior Distributions

The **PRIOR** statement is used to specify the prior distribution of the model parameters. You must specify a list of parameters, a tilde (~), and then a distribution with its parameters. You can specify multiple **PRIOR** statements to define independent prior distributions. Parameters that are associated with a regressor variable are referred to by the name of the corresponding regressor variable. For information about how parameters are named so that you can refer to them when specifying prior distributions, see the section “[Naming of Parameters](#)” on page 614. Alternatively, the **SHOWNAMES** suboption of the **PRIORSUMMARY** option displays the names that are used in all parameters in the prior summary table.

If a parameter is not associated with a **PRIOR** statement, then the default choices shown in [Table 12.4](#) are used.

Table 12.4 Default Values for Prior Distributions

Parameter Type	Default Prior Name	Default Prior Specification
Regression, location	Normal	NORMAL(MEAN=0, VAR=1E6)
Scale, SD	Truncated normal	NORMAL(MEAN=0, VAR=1E6, LOWER=0, UPPER=INF)

For more information about each prior density, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).” For information about truncated densities, see the section “[Truncated Prior Distributions](#)” on page 609. For information about why the default prior on the standard deviation parameter is a truncated normal distribution, see the section “[Prior Distributions for Scale Parameters](#)” on page 608.

Prior Distributions for Scale Parameters

A common choice for a prior distribution on variance parameters and other scale parameters is the inverse gamma distribution. This prior can often be problematic in practice, and as a consequence it can even cause computational problems. This is partially because the density puts essentially no probability mass near zero. For more information, see Gelman (2006). The main advantage of the inverse gamma prior is that it is the conditionally conjugate prior for a variance parameter in a normal model; this makes certain sampling algorithms easier to use. For more information, see the section “[Conjugate Priors](#)” on page 9 in Chapter 2,

“[Introduction to Bayesian Analysis Procedures](#).” However, the posterior sampler in PROC CQLIM does not take advantage of this conjugacy, so there is no computational benefit to using the inverse gamma prior.

Instead, PROC CQLIM uses the half-normal distribution for the default prior on standard deviation parameters—that is, a mean zero normal distribution truncated from below at zero. This density allows for the standard deviation parameter to be estimated arbitrarily close to zero and otherwise removes the problems associated with the inverse gamma prior. In general, if you want to specify prior information on the standard deviation parameter or some other scale parameter, it is recommended that you encode that information into a truncated normal distribution or perhaps a truncated t distribution.

If you want to specify the classic inverse gamma prior for a variance parameter, note that PROC CQLIM is parameterized in terms of the standard deviation parameter. So instead, the square root inverse gamma prior should be used on `_Sigma`, the standard deviation parameter in most models in PROC CQLIM.

Truncated Prior Distributions

All prior distributions except the uniform distribution can be turned into truncated prior distributions by using the LOWER and UPPER parameters. By default, LOWER is set to the maximum of the parameter’s lower bound and the specified prior distribution’s lower bound, and UPPER is set to the minimum of the parameter’s upper bound and the specified prior distribution’s upper bound. For example, for `_Sigma`, the standard deviation parameter in a regression model, the following statement specifies a truncated normal prior on `_Sigma` with LOWER=0 and UPPER=INFINITY:

```
prior _Sigma ~ normal(mean = 0, var = 1);
```

The density for of truncated prior can be computed from the corresponding untruncated density given in the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#),” as follows. Suppose $\pi(\theta)$ is the prior density for the parameter θ . Then let $\Pi(\theta)$ denote the corresponding CDF, defined by the integral

$$\Pi(\theta) = \int_{-\infty}^{\theta} \pi(x) dx$$

where $\pi(x)$ is taken to be 0 outside its range (for each prior density’s range, see the section “[Standard Prior Distributions](#)” on page 12 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#)”). Then the truncated density is constructed from the untruncated density by using the formula

$$\pi_{L,U}(\theta) = \frac{\pi(\theta)}{\Pi(U) - \Pi(L)}$$

where $L < U$ are the lower and upper truncation bounds, respectively. If the lower truncation bound is the lower bound of π ’s range, then $\Pi(L) = 0$, and similarly if the upper truncation bound is the upper bound of π ’s range, then $\Pi(U) = 1$.

Output to SAS Data Table

XBeta, Predicted, and Residual

XBeta is the structural part on the right-hand side of the model. The predicted value is the predicted dependent variable value. For censored variables, if the predicted value is outside the boundaries, it is reported as the closest boundary. For discrete variables, it is the level whose boundaries Xbeta falls between. The residual is defined only for continuous variables and is defined as

$$\text{Residual} = \text{Observed} - \text{Predicted}$$

Error Standard Deviation

The error standard deviation is σ_i in the model. It varies only when the HETERO statement is used.

Marginal Effects

A marginal effect is defined as a contribution of one control variable to the response variable. For a binary choice model with two response categories, $\mu_0 = -\infty$, $\mu_1 = 0$, and $\mu_2 = \infty$. For an ordinal response model with M response categories ($\mu_0, \dots, \mu_M$), define

$$R_{i,j} = \mu_j - \mathbf{x}_i' \boldsymbol{\beta}$$

The probability that the unobserved dependent variable is contained in the j th category can be written as

$$P[\mu_{j-1} < y_i^* \leq \mu_j] = F(R_{i,j}) - F(R_{i,j-1})$$

The marginal effect of changes in the regressors on the probability of $y_i = j$ is then

$$\frac{\partial \text{Prob}[y_i = j]}{\partial \mathbf{x}} = [f(\mu_{j-1} - \mathbf{x}_i' \boldsymbol{\beta}) - f(\mu_j - \mathbf{x}_i' \boldsymbol{\beta})] \boldsymbol{\beta}$$

where $f(x) = \frac{dF(x)}{dx}$. In particular,

$$f(x) = \frac{dF(x)}{dx} = \begin{cases} \frac{1}{\sqrt{2\pi}} e^{-x^2/2} & (\text{probit}) \\ \frac{e^{-x}}{[1+e^{(-x)}]^2} & (\text{logit}) \end{cases}$$

The marginal effects in the truncated regression model are

$$\frac{\partial E[y_i | L_i < y_i^* < R_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \left[1 - \frac{(\phi(a_i) - \phi(b_i))^2}{(\Phi(b_i) - \Phi(a_i))^2} + \frac{a_i \phi(a_i) - b_i \phi(b_i)}{\Phi(b_i) - \Phi(a_i)} \right]$$

where $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$.

The marginal effects in the censored regression model are

$$\frac{\partial E[y | \mathbf{x}_i]}{\partial \mathbf{x}} = \boldsymbol{\beta} \times \text{Prob}[L_i < y_i^* < R_i]$$

For models that involve higher-order or interaction variables, the marginal effects are calculated by treating these variables as independent explanatory variables. Therefore, the marginal effects of the higher-order or interaction variables ignore the polynomial nature of these variables.

Inverse Mills Ratio, Expected and Conditionally Expected Values

Expected and conditionally expected values are computed only for continuous variables. The inverse Mills ratio is computed for censored or truncated continuous, binary discrete, and selection endogenous variables.

Let L_i and R_i be the lower boundary and the upper boundary of y_i . Define $a_i = \frac{L_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$ and $b_i = \frac{R_i - \mathbf{x}_i' \boldsymbol{\beta}}{\sigma_i}$. Then the inverse Mills ratio is defined as

$$\lambda = \frac{(\phi(a_i) - \phi(b_i))}{(\Phi(b_i) - \Phi(a_i))}$$

for a continuous variable and defined as

$$\lambda = \frac{\phi(\mathbf{x}_i' \boldsymbol{\beta})}{\Phi(\mathbf{x}_i' \boldsymbol{\beta})}$$

for a binary discrete variable.

The expected value is the unconditional expectation of the dependent variable. For a censored variable, it is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)(\Phi(b_i) - \Phi(a_i)) + (1 - \Phi(b_i))R_i$$

For a left-censored variable ($R_i = \infty$), this formula is

$$E[y_i] = \Phi(a_i)L_i + (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)(1 - \Phi(a_i))$$

where $\lambda = \frac{\phi(a_i)}{1 - \Phi(a_i)}$.

For a right-censored variable ($L_i = -\infty$), this formula is

$$E[y_i] = (\mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i)\Phi(b_i) + (1 - \Phi(b_i))R_i$$

where $\lambda = -\frac{\phi(b_i)}{\Phi(b_i)}$.

For a noncensored variable, this formula is

$$E[y_i] = \mathbf{x}_i' \boldsymbol{\beta}$$

The conditional expected value is the expectation given that the variable is inside the boundaries:

$$E[y_i | L_i < y_i < R_i] = \mathbf{x}_i' \boldsymbol{\beta} + \lambda\sigma_i$$

Probability

Probability applies only to discrete responses. It is the marginal probability that the discrete response is taking the value of the observation. If you specify the PROBALL option, then the probability for all possible responses of the discrete variables is computed.

Technical Efficiency

Technical efficiency for each producer is computed only for stochastic frontier models.

In general, the stochastic production frontier can be written as

$$y_i = f(x_i; \beta) \exp\{v_i\} TE_i$$

where y_i denotes producer i 's actual output, $f(\cdot)$ is the deterministic part of the production frontier, $\exp\{v_i\}$ is a producer-specific error term, and TE_i is the technical efficiency coefficient, which can be written as

$$TE_i = \frac{y_i}{f(x_i; \beta) \exp\{v_i\}}$$

For a Cobb-Douglas production function, $TE_i = \exp\{-u_i\}$. For more information, see the section “[Stochastic Frontier Production and Cost Models](#)” on page 600.

The cost frontier can be written in general as

$$E_i = c(y_i, w_i; \beta) \exp\{v_i\} / CE_i$$

where w_i denotes producer i 's input prices, $c(\cdot)$ is the deterministic part of the cost frontier, $\exp\{v_i\}$ is a producer-specific error term, and CE_i is the cost efficiency coefficient, which can be written as

$$CE_i = \frac{c(x_i, w_i; \beta) \exp\{v_i\}}{E_i}$$

For a Cobb-Douglas cost function, $CE_i = \exp\{-u_i\}$. For more information, see the section “[Stochastic Frontier Production and Cost Models](#)” on page 600. Hence, both technical and cost efficiency coefficients are the same. The estimates of technical efficiency are provided in the following subsections.

Normal-Half-Normal Model

Define $\mu_* = -\epsilon\sigma_u^2/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as shown by Jondrow et al. (1982), conditional density is as follows:

$$f(u|\epsilon) = \frac{f(u, \epsilon)}{f(\epsilon)} = \frac{1}{\sqrt{2\pi}\sigma_*} \exp\left\{-\frac{(u - \mu_*)^2}{2\sigma_*^2}\right\} \Bigg/ \left[1 - \Phi\left(-\frac{\mu_*}{\sigma_*}\right)\right]$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\mu_*, \sigma_*^2)$.

From this result, it follows that the estimate of technical efficiency (Battese and Coelli 1988) is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_* - \mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right] \exp\left\{-\mu_{*i} + \frac{1}{2}\sigma_*^2\right\}$$

The second version of the estimate (Jondrow et al. 1982) is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \mu_{*i} + \sigma_* \left[\frac{\phi(-\mu_{*i}/\sigma_*)}{1 - \Phi(-\mu_{*i}/\sigma_*)} \right] = \sigma_* \left[\frac{\phi(\epsilon_i \lambda / \sigma)}{1 - \Phi(\epsilon_i \lambda / \sigma)} - \left(\frac{\epsilon_i \lambda}{\sigma} \right) \right]$$

Normal-Exponential Model

Define $A = -\tilde{\mu}/\sigma_v$ and $\tilde{\mu} = -\epsilon - \sigma_v^2/\sigma_u$. Then, as shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_v\Phi(-\tilde{\mu}/\sigma_v)} \exp\left\{-\frac{(u - \tilde{\mu})^2}{2\sigma^2}\right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_v^2)$.

From this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \left[\frac{1 - \Phi(\sigma_v - \tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] \exp\left\{-\tilde{\mu}_i + \frac{1}{2}\sigma_v^2\right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_v \left[\frac{\phi(-\tilde{\mu}_i/\sigma_v)}{1 - \Phi(-\tilde{\mu}_i/\sigma_v)} \right] = \sigma_v \left[\frac{\phi(A)}{\Phi(-A)} - A \right]$$

Normal-Truncated Normal Model

Define $\tilde{\mu} = (-\sigma_u^2\epsilon_i + \mu\sigma_v^2)/\sigma^2$ and $\sigma_*^2 = \sigma_u^2\sigma_v^2/\sigma^2$. Then, as shown by Kumbhakar and Lovell (2000), conditional density is as follows:

$$f(u|\epsilon) = \frac{1}{\sqrt{2\pi}\sigma_*[1 - \Phi(-\tilde{\mu}/\sigma_*)]} \exp\left\{-\frac{(u - \tilde{\mu})^2}{2\sigma_*^2}\right\}$$

Hence, $f(u|\epsilon)$ is the density for $N^+(\tilde{\mu}, \sigma_*^2)$.

From this result, it follows that the estimate of technical efficiency is

$$TE1_i = E(\exp\{-u_i\}|\epsilon_i) = \frac{1 - \Phi(\sigma_* - \tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \exp\left\{-\tilde{\mu}_i + \frac{1}{2}\sigma_*^2\right\}$$

The second version of the estimate is

$$TE2_i = \exp\{-E(u_i|\epsilon_i)\}$$

where

$$E(u_i|\epsilon_i) = \tilde{\mu}_i + \sigma_* \left[\frac{\phi(\tilde{\mu}_i/\sigma_*)}{1 - \Phi(-\tilde{\mu}_i/\sigma_*)} \right]$$

Naming

Naming of Parameters

When the estimation contains only one equation, the parameters are named in the same way as in other SAS procedures, such as the REG and PROBIT procedures. The constant in the regression equation is named Intercept. The coefficients of independent variables are named by the independent variables. The standard deviation of the errors is called `_Sigma`. The limits of the discrete dependent variable are named `_Limiti`. `_Limit1` is set to 0 and the limit parameters start from $i = 2$. If you also specify the HETERO statement, the coefficients of the independent variables in the HETERO statement are called `_H.x`, where x is the name of the independent variable.

When the estimation contains multiple equations, the parameters in the main equation are named in the format of `y.x`, where y is the name of the dependent variable and x is the name of the independent variable. The standard deviation of the errors is named `_Sigma.y`. The correlation of the errors is named `_Rho` for the bivariate model. For the model that contains three variables, it is `_Rho.y1.y2`, `_Rho.y1.y3`, and `_Rho.y2.y3`. The construction of correlation names for models that contain four or more variables is analogous.

Naming of Output Variables

Table 12.5 shows the *options* in the OUTPUT statement, along with the corresponding variable names and their explanations.

Table 12.5 OUTPUT Statement Options

<i>output-option</i>	Variable Name	Explanation
CONDITIONAL	CEXPCT_y	Conditional expected value of y , conditioned on the truncation
ERRSTD	ERRSTD_y	Standard deviation of error term
EXPECTED	EXPCT_y	Unconditional expected value of y
MARGINAL	MEFF_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with single equation
	MEFF_y_x	Marginal effect of x on y ($\frac{\partial y}{\partial x}$) with multiple equations
	MEFF_Pi_x	Marginal effect of x on y ($\frac{\partial \text{Prob}(y=i)}{\partial x}$) with single equation and discrete y
	MEFF_Pi_y_x	Marginal effect of x on y ($\frac{\partial \text{Prob}(y=i)}{\partial x}$) with multiple equations and discrete y
MILLS	MILLS_y	Inverse Mills ratio for y
PREDICTED	P_y	Predicted value of y
PROB	PROB_y	Probability that y is taking the observed value in this observation (discrete y only)
PROBALL	PROB_i_y	Probability that y is taking the i th value (discrete y only)
RESIDUAL	RESID_y	Residual of y , ($y - \text{PredictedY}$)
TE1	TE1	Technical efficiency estimate for each producer proposed by Battese and Coelli (1988)

Table 12.5 *continued*

<i>output-option</i>	Variable Name	Explanation
TE2	TE2	Technical efficiency estimate for each producer proposed by Jondrow et al. (1982)
XBETA	XBETA_y	Structure part ($\mathbf{x}'\boldsymbol{\beta}$) of y equation

ODS Table Names

PROC CQLIM assigns a name to each table that it creates. You can use these names to refer to the tables when you use the Output Delivery System (ODS) to select tables and create output data tables. These names are listed in Table 12.6.

Table 12.6 ODS Tables Produced by PROC CQLIM

Table Name	Description	Statement	Option

Examples: The CQLIM Procedure

Example 12.1: Model with Censoring

This example uses the CQLIM procedure to process a large data table.

The following DATA step generates a data set that contains 5 million observations from a censored model. The model contains seven variables.

```
data simulate;
  call streaminit(12345);
  array vars x1-x7;
  array parms{7} (3 4 2 4 -3 -5 -3);
  intercept = 2;
  do i = 1 to 5000000;
    sum_xb = 0;
    do j = 1 to 7;
      vars[j] = rand('NORMAL', 0, 1);
      sum_xb = sum_xb + parms[j] * vars[j];
    end;
    y = intercept + sum_xb + 100 * rand('NORMAL', 0, 1);
    if y > 400 then y = 400;
    if y < 0 then y = 0;
    output;
  end;
  keep y x1-x7;
run;
```

You can load the data set simulate into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.simulate;
  set simulate;
run;
```

The following statements estimate a censored model:

```
proc cqlim data = mylib.simulate;
  model y = x1-x7 / censored(lb = 0 ub = 400);
run;
```

Output 12.1.1 shows the estimation results for the censored model. The “Model Fit Summary” table shows detailed information about the model. All parameter estimates in the “Parameter Estimates” table are highly significant and correspond to their theoretical values that were set during the data generating process.

Output 12.1.1 Censored Model: Summary

Example 12.2: Bivariate Probit Analysis

This example shows how to estimate a bivariate probit model by using a large data table.

The following DATA step generates a data set that contains 1 million observations from a bivariate probit model:

```
data bivariate_probit;
  call streaminit(19283);
  keep y1 y2 x1 x2;
  do i = 1 to 1000000;
    x1 = rand('NORMAL', 0, 1);
    x2 = rand('NORMAL', 0, 1);
    u1 = rand('NORMAL', 0, 1);
    u2 = rand('NORMAL', 0, 1);
    y1l = 1 + 2 * x1 + 3 * x2 + u1;
    y2l = 3 + 4 * x1 - 2 * x2 + u1 * 0.2 + u2;
    if y1l > 0 then y1 = 1;
    else y1 = 0;
    if y2l > 0 then y2 = 1;
    else y2 = 0;
    output;
  end;
run;
```

You can load the data set `bivariate_probit` into a data table in your session that is associated with the `mylib` libref. The DATA step assumes that your libref is named `mylib`, but you can substitute any appropriately defined libref.

```
data mylib.bivariate_probit;
    set bivariate_probit;
run;
```

The following statements estimate a bivariate probit model. Note that the INIT statement in the SAS program sets the initial values for some parameters in the optimization. The METHOD=QN option specifies the quasi-Newton optimization algorithm.

```
proc cqlim data = mylib.bivariate_probit method = qn;
    init y1.x1 = 2.8, y1.x2 = 2.1, _rho = 0.1;
    model y1 = x1 x2 / discrete;
    model y2 = x1 x2 / discrete;
run;
```

Output 12.2.1 shows the estimation results for the bivariate probit model. The “Discrete Response Profile” tables show the response profile for the variables y_1 and y_2 .

Example 12.3: Bayesian Analysis

This example uses the CQLIM procedure to process a small data table.

The following DATA step generates a data set that contains 1,000 observations from a censored model. The model contains eight variables.

```
data bayes_ex;
  call streaminit(12345);
  array vars x1-x7;
  array parms{7} (3 4 2 4 -3 -5 -3);
  intercept1 = 0;
  intercept2 = 4;
  intercept3 = 10;
  do i = 1 to 1000;
    sum_xb = 0;
    do j = 1 to 7;
      vars[j] = rand('NORMAL', 0, 1);
      sum_xb = sum_xb + parms[j] * vars[j];
    end;
    g = rand('NORMAL', 0, 1);
    if g < -0.5 then intercept = intercept1;
    if g >= -0.5 then intercept = intercept2;
    if g > 0.5 then intercept = intercept3;
    y = intercept + sum_xb + 10 * rand('NORMAL', 0, 1);
    if y > 400 then y = 400;
    if y < 0 then y = 0;
    if g < -0.5 then group = 0;
    if g >= -0.5 then group = 1;
    if g > 0.5 then group = 2;
    output;
  end;
  keep y x1-x7 group;
run;
```

You can load the data set bayes_ex into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.bayes_ex;
  set bayes_ex;
run;
```

The following statements estimate a censored model by using Bayesian methods. Note that the BAYES statement controls the settings for the MCMC sampler and determines which Bayesian output is produced. The NCHAIN= option controls the number of Markov chains, and the NSAMPLE= option controls the size of the posterior sample per chain. The PRIOR statements set the prior distributions for the parameters.

```
proc cqlim data = mylib.bayes_ex;
  class group;
  model y = x1-x7 group / censored(lb = 0 ub = 400);
  bayes priorsummary(shownames) seed = 72342 nsample = 10000 nchain = 4
        sampler = rwm(ntune = 100 ntunestage = 20);
  prior intercept ~ normal(mean = 0, sd = 100);
  prior x1-x5 ~ normal(mean = 0, sd = 10);
  prior x6 ~ t(loc = 0, scale = 10, df = 3, lower = 0);
  prior group_0 ~ normal(mean = -4, var = 100);
  prior _sigma ~ normal(mean = 0, sd = 100);
run;
```

Output 12.3.1 shows the Bayesian estimation results for the censored model. The “Prior Summary” table shows detailed information about prior distributions for the parameters in the model. The “Posterior Summaries” table contains two point estimates of the parameters from the posterior samples: the posterior mean and the posterior median (50th percentile). The “MCMC Diagnostics Summaries” table contains basic convergence diagnostics to check whether the Markov chain has converged and whether the sample size is sufficient.

Example 12.4: Marginal Effects Using Bayesian Analysis with NUTS

This example uses the CQLIM procedure to process a small data table.

The following DATA step generates a data set that contains 5,000 observations from a logistic regression model. The model contains seven variables.

```
data nuts_ex;
  call streaminit(784923);
  array vars x1-x7;
  array slopes{8} (0.03 0.04 0.02 0.04 -0.03 -0.05 -0.03 0.01);
  intercept = 2;

  do i = 1 to 5000;
    sum_xb = intercept;
    do j=1 to 7;
      vars[j] = rand('NORMAL',0,1);
      sum_xb = sum_xb + slopes[j] * vars[j];
    end;
    sum_xb = sum_xb + vars[1] * vars[1] * slopes[8];
    u = rand('UNIFORM');
    z = sum_xb + log(u) - log(1-u);
    if z > 0 then y = 1;
    if z <= 0 then y = 0;
    output;
  end;
  keep y x1-x7;
run;
```

You can load the data set nuts_ex into a data table in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```
data mylib.nuts_ex;
  set nuts_ex;
run;
```

The following statements estimate a logistic regression model in the Bayesian framework by using the No-U-Turn Sampler (NUTS). The model includes a second-order term for the covariate x1. The **NCHAIN=** option controls the number of Markov chains, and the **NSAMPLE=** option controls the size of the posterior sample per chain. NUTS is specified in the **SAMPLER=** option, and several values controlling the sampler can be set as arguments to **SAMPLER=NUTS**. The **OUTPOST=** option creates a CAS table that contains the posterior sample, which in this case is named nuts_post.

```
proc cqlim data = mylib.nuts_ex;
  model y = x1-x7 x1*x1 / discrete(distribution = logistic);
  bayes seed = 72342 nsample = 2000 nchain = 4 sampler = nuts(ntune = 2000)
    outpost = mylib.nuts_post;
  prior intercept ~ normal(mean = 0, sd = 1000);
  prior x1-x7 ~ normal(mean = 0, sd = 100);
  prior x1__x1 ~ normal(mean = 0, sd = 10);
run;
```

Output 12.4.1 shows the Bayesian estimation results for the logistic regression model. The “Posterior Summaries” table contains two point estimates of the parameters from the posterior samples: the posterior mean and the posterior median (50th percentile). The “MCMC Diagnostics Summaries” table contains basic convergence diagnostics to check whether the Markov chain has converged and whether the sample size is sufficient.

The following sequence of statements computes the posterior sample of the sample mean marginal effects for each of the covariates in the model. In binary choice models, the marginal effect of the j th covariate on the i th observation is given by the derivative of i 's choice probability with respect to the j th covariate, evaluated at i 's value of that covariate. For logistic regression, this is given by

$$\frac{\partial}{\partial x_{ij}} P(y_i = 1) = \frac{\partial}{\partial x_{ij}} \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta})}{1 + \exp(\mathbf{x}'_i \boldsymbol{\beta})} = \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta})}{[1 + \exp(\mathbf{x}'_i \boldsymbol{\beta})]^2} \beta_j$$

The model includes a squared term for the covariate x1. Rewrite $\mathbf{x}'_i \boldsymbol{\beta}$ as $\mathbf{x}'_i \boldsymbol{\beta} + x_{i1}^2 \alpha$ to make the squared term explicit. Then the marginal effect of the covariate x1 is given by

$$\frac{\partial}{\partial x_{i1}} P(y_i = 1) = \frac{\partial}{\partial x_{i1}} \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta} + x_{i1}^2 \alpha)}{1 + \exp(\mathbf{x}'_i \boldsymbol{\beta} + x_{i1}^2 \alpha)} = \frac{\exp(\mathbf{x}'_i \boldsymbol{\beta} + x_{i1}^2 \alpha)}{[1 + \exp(\mathbf{x}'_i \boldsymbol{\beta} + x_{i1}^2 \alpha)]^2} (\beta_j + 2x_{i1} \alpha)$$

The sample mean marginal effect is the mean of these individual marginal effects over all observations in the data set. These mean marginal effects must be computed for each iteration in the posterior sample to obtain the posterior distribution of the mean marginal effects.

The first set of statements computes the sample mean marginal effects for each iteration in the posterior distribution:

```

proc cas;
  fedSql.execDirect / query =
    "create table nuts_marginaleffects {options replace=true} as
    select avg(gradprob * (b_x1 + 2 * x1 * b_x1__x1)) as me_x1,
          avg(gradprob * b_x2) as me_x2,
          avg(gradprob * b_x3) as me_x3,
          avg(gradprob * b_x4) as me_x4,
          avg(gradprob * b_x5) as me_x5,
          avg(gradprob * b_x6) as me_x6,
          avg(gradprob * b_x7) as me_x7 from
    (
      select exp(xbeta) / (1 + exp(xbeta))**2 as gradprob, * from
      (
        select b.Intercept + a.x1 * b.x1 + a.x2 * b.x2 + a.x3 * b.x3 +
              a.x4 * b.x4 + a.x5 * b.x5 + a.x6 * b.x6 + a.x7 * b.x7 +
              a.x1 * a.x1 * b.x1__x1 as xbeta,
              a.*, b.Chain, b.Iteration, b.Intercept, b.x1__x1 as b_x1__x1,
              b.x1 as b_x1, b.x2 as b_x2, b.x3 as b_x3, b.x4 as b_x4,
              b.x5 as b_x5, b.x6 as b_x6, b.x7 as b_x7
        from nuts_ex as a, nuts_post as b
      ) as c
    ) as d
    group by Chain, Iteration;";
run; quit;

```

The last set of statements uses several actions to compute summary statistics of the posterior distribution of the mean marginal effects, including posterior means, standard deviations, and percentiles:

```

proc cas;
  simple.summary / table = {name = "nuts_marginaleffects"},
    inputs = {"me_x1", "me_x2", "me_x3", "me_x4", "me_x5", "me_x6", "me_x7"},
    subSet = {"N", "mean", "std"};
  casout = {name = "nuts_me_summary", replace = True};
  percentile.percentile / table = {name = "nuts_marginaleffects"},
    inputs = {"me_x1", "me_x2", "me_x3", "me_x4", "me_x5", "me_x6", "me_x7"},
    values = {2.5, 25, 50, 75, 97.5};
  casout = {name = "nuts_me_percentiles", replace = True};
  transpose.transpose / table = {name = "nuts_me_percentiles",
    groupby = {"_Column_"}}, transpose = {"_Value_"}, prefix = "Pct_",
    id = {"_Pctl_"}, casout = {name = "nuts_me_percentiles", replace = True};
  table.alterTable / name = "nuts_me_percentiles",
    drop = "_NAME_",
    columns = {{name = "_Column_", rename = "Parameter"},
      {name = "Pct_2.5", rename = "Pct_2_5",
        label = "2.5%", format = "D8."},
      {name = "Pct_25", label = "25%", format = "D8."},
      {name = "Pct_50", label = "50%", format = "D8."},
      {name = "Pct_75", label = "75%", format = "D8."},
      {name = "Pct_97.5", rename = "Pct_97_5",
        label = "97.5%", format = "D8."}};
  table.alterTable / name = "nuts_me_summary",
    columns = {{name = "_Column_", rename = "Parameter"},
      {name = "_NObs_", rename = "N"}},

```

```

        {name = "_Mean_", rename = "Mean", format = "D8."},
        {name = "_Std_", rename = "Std",
          label = "Standard Deviation", format = "D8."}};
fedSql.execDirect / query =
  "create table nuts_me_post_summary(options replace = true) as
  select a.*, b.Pct_2_5, b.Pct_25, b.Pct_50, b.Pct_75, b.Pct_97_5 from
  nuts_me_summary as a, nuts_me_percentiles as b
  where a.Parameter = b.Parameter";
table.fetch / table = {name = "nuts_me_post_summary"},
  index = False, sortby = "Parameter";
run;
quit;

```

Output 12.4.2 shows the posterior summary of the mean marginal effects.

Output 12.4.2 Posterior Summary of Mean Marginal Effects

Results from table.fetch

Example 12.5: Bayesian Analysis with Multiple Chains

This example shows how to perform Bayesian analysis with multiple chains in the CQLIM procedure by using a small data table.

The following DATA step creates the Christenson Associates airline data, a frequently cited data set (Greene 2000). The data measure the costs, prices of inputs, and utilization rates for six airlines from 1970 to 1984. This example analyzes the log transformations of cost (C), quantity (Q), and price (PF) and the untransformed load factor (LF). These statements assume that your libref is named mylib, but you can substitute any appropriately defined libref.

```

data mylib.airline;
  input Obs AirlineID T C Q PF LF;
  Year = T + 1969;
  lC   = log(C);
  lQ   = log(Q);
  lPF  = log(PF);
  label lC   = "Log Transformation of Costs";
  label lQ   = "Log Transformation of Quantity";
  label lPF  = "Log Transformation of Price of Fuel";
  label LF   = "Load Factor (utilization index)";
datalines;
1   1   1   1140640   0.95276   106650   0.53449
2   1   2   1215690   0.98676   110307   0.53233
3   1   3   1309570   1.09198   110574   0.54774
4   1   4   1511530   1.17578   121974   0.54085
5   1   5   1676730   1.16017   196606   0.59117
... more lines ...

```

The following statements estimate a simple linear regression model in the Bayesian framework by using the No-U-Turn Sampler (NUTS). NUTS is specified in the **SAMPLER=** option, and several values controlling the sampler can be set as arguments to **SAMPLER=NUTS**. The **NCHAIN=** option controls the number of Markov chains, and the **NSAMPLE=** option controls the size of the posterior sample per chain. PROC CQLIM automatically aggregates the results of each of the chains to create the posterior statistics and MCMC diagnostics tables that you request. The **BYCHAIN** suboption of the **STATISTICS=** and **DIAGNOSTICS=** options additionally produces those tables separately for each chain. This example produces the “Posterior Summaries” table, the “MCMC Diagnostic Summaries” table, and the “Heidelberger-Welch Diagnostics” table for each chain as well as for all chains combined.

```
proc cqlim data = mylib.airline;
  model lC = lQ lPF lF;
  bayes seed = 2358 nsample = 2000 nchain = 4
    sampler = nuts(ntune = 2000)
    statistics(bychain) = summary
    diagnostics(bychain) = (summary heidel);
run;
```

Output 12.5.1 shows the Bayesian estimation results. The “Posterior Summaries” table contains the estimates of the posterior mean and posterior quantiles computed using all four chains. The other posterior summary statistics tables that are produced by the **STATISTICS=** option would similarly be computed using all four chains. The “MCMC Diagnostic Summaries” table contains basic convergence diagnostics aggregated across all four chains. The “Autocorrelation Diagnostics” table would also be aggregated for multiple chains. For more information about how this aggregation is performed, see the section “Using Multiple Chains” on page 37 in Chapter 2, “Introduction to Bayesian Analysis Procedures.” The “Heidelberger-Welch Diagnostics” table displays a summary of all the Heidelberger-Welch tests performed for each chain. Specifically, it shows the number of chains for which each test passed for each parameter, as well as the largest number of iterations that were discarded for the stationarity test. The “Geweke Diagnostics” table and the “Raftery-Lewis Diagnostics” table both would be summarized similarly.

Output 12.5.1 Posterior Summaries and MCMC Diagnostics

The CQLIM Procedure

Detailed results for each chain are available in [Output 12.5.2](#) as a result of the BYCHAIN options. The “Posterior Summaries by Chain” table contains the estimates of the posterior mean and posterior quantiles computed separately for each chain. Similarly, the “MCMC Diagnostic Summaries by Chain” table contains basic convergence diagnostics computed for each chain, and the “Heidelberger-Welch Diagnostics by Chain” table contains the Heidelberger-Welch diagnostics computed for each chain. For more information about the differences between the tables in [Output 12.5.1](#) and [Output 12.5.2](#), see the section “[Using Multiple Chains](#)” on page 37 in Chapter 2, “[Introduction to Bayesian Analysis Procedures](#).”

Overview: CSPATIALREG Procedure

The CSPATIALREG (spatial regression) procedure, in SAS Viya, analyzes a class of linear spatial econometric models for cross-sectional data whose observations are spatially referenced or georeferenced. For example, housing price data that are collected from the 48 contiguous US states fall into the category of spatially referenced data. Compared to nonspatial regression models, spatial econometric models are capable of handling spatial interaction and spatial heterogeneity in a regression setting (Anselin 2001).

Spatial econometric models have been widely used in economics, political science, sociology, and other fields. For example, LeSage and Pace (2009) provide a detailed introduction to commonly used spatial econometric models from both frequentist and Bayesian perspectives. A brief introduction to spatial econometric models is also provided by Elhorst (2013).

PROC CSPATIALREG Features

The CSPATIALREG procedure fits spatial data regression models by maximum likelihood techniques.

PROC CSPATIALREG supports the following models:

- linear model
- linear model with spatial lag of X (SLX) effects
- spatial autoregressive (SAR) model
- spatial Durbin model (SDM)
- spatial error model (SEM)
- spatial Durbin error model (SDEM)
- spatial moving average (SMA) model
- spatial Durbin moving average (SDMA) model
- spatial autoregressive moving average (SARMA) model
- spatial Durbin autoregressive moving average (SDARMA) model
- spatial autoregressive confused (SAC) model
- spatial Durbin autoregressive confused (SDAC) model
- conditional autoregressive (CAR) model
- conditional autoregressive model with spatially lagged covariates (CAR2)

The following list summarizes some basic features of the CSPATIALREG procedure:

- uses model-building syntax that includes CLASS and effect-based MODEL statements that are familiar from other SAS Econometrics analytic procedures
- enables you to fit various models by using maximum likelihood estimation
- provides a **TEST** statement for performing linear tests of hypotheses
- provides a **RESTRICT** statement for imposing linear parameter constraints
- provides an **OUTPUT** statement for producing a data table that contains predictions and residuals
- enables you to fit multiple models, compare their fit statistics, and select the best fit by using criteria such as AIC and SBC

Because the CSPATIALREG procedure runs on SAS Cloud Analytic Services (CAS), it also does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- enables you to run in single-machine mode
- exploits all the available cores and concurrent threads. For information about how PROC CSPATIALREG uses threads, see the section “[Multithreading](#)” on page 108 in Chapter 4, “[Shared Concepts](#).”

PROC CSPATIALREG Compared with the SPATIALREG Procedure

The CSPATIALREG procedure is specifically designed to operate on SAS Viya and performs computations in multiple threads on multiple machines. In comparison, the SPATIALREG procedure executes in multiple threads on a single machine. The CSPATIALREG procedure models cross-sectional data in a way that is similar to how the SPATIALREG procedure in SAS/ETS software models them.

The CSPATIALREG procedure now supports all the models that are supported by PROC SPATIALREG and new conditional autoregressive (CAR) models that are not supported by PROC SPATIALREG. In addition, PROC CSPATIALREG supports impact estimation for the following models: CAR, linear, SAC, SAR, SARMA, SDAC, SDARMA, SDEM, SDM, SDMA, SEM, SMA, and SLX models. Furthermore, PROC CSPATIALREG supports the fitting and comparison of multiple models. PROC SPATIALREG does not provide any of this support.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the `CASHOST` and `CASPORT` of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the `TERMINATE` option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: CSPATIALREG Procedure

NOTE: Input data must be in a CAS table that is accessible in your CAS session. You must refer to this table by using a two-level name. The first level must be a CAS engine libref, and the second level must be the table name. For more information, see the sections “[Using CAS Sessions and CAS Engine Librefs](#)” on page 54 and “[Loading a SAS Data Set onto a CAS Server](#)” on page 55 in Chapter 4, “[Shared Concepts](#).”

The CSPATIALREG procedure is similar to other SAS regression model procedures for nonspatial data, except that in PROC CSPATIALREG you usually need to provide a secondary data table (in the WMAT= option), which provides information about spatial weights matrix. The spatial weights matrix defines all pairwise spatial relationships and is a vital component of a spatial econometric model. For more information about how to create spatial weights matrix, see the section “[Specifying the Spatial Weights Matrix](#)” on page 671.

The following statements fit a SAR model:

```
proc cspatialreg data=mylib.One Wmat=mylib.W;
  model y = x1 x2 / type=SAR;
  spatialid sid;
run;
```

The response variable *y* (a continuous variable) and the explanatory variables *x1* and *x2* are contained in the data table *mylib.One*. The spatial weights matrix that you specify using the WMAT= option defines neighbor relationships among all spatial units in the data. The SPATIALID statement specifies a spatial ID variable that identifies spatial units in two data tables that you provide in the DATA= and WMAT= options. You specify the TYPE=SAR option in the MODEL statement to request a SAR model.

The following example illustrates PROC CSPATIALREG by using a real-world data set. The data set *CrimeOH* is taken from Anselin (1988). This data set contains variables such as *Income* (household income, measured in \$1,000), *HValue* (housing value by \$1,000), and *Crime* (number of crimes, including residential burglaries and vehicle thefts, measured per 1,000 households) in 49 neighborhoods in Columbus, Ohio. You want to examine how household income and housing value affect the number of crimes in these neighborhoods.

The first 10 observations in the *mylib.CrimeOH* data set are shown in [Figure 13.1](#).

Figure 13.1 Columbus Crime Data

Obs	crime	income	hvalue	lat	lon	sid
1	18.802	21.232	44.567	35.62	42.38	s1
2	0.178	8.438	75.000	33.36	38.41	s4
3	50.732	11.252	23.225	40.01	38.00	s7
4	34.001	13.598	96.400	47.61	36.42	s10
5	19.146	18.942	40.300	50.11	29.91	s13
6	16.241	29.833	61.950	48.44	27.93	s16
7	33.705	11.709	30.450	43.37	33.46	s19
8	41.968	9.918	23.600	44.10	30.40	s22
9	25.962	16.961	33.500	43.23	27.31	s25
10	29.028	14.135	27.733	39.32	25.85	s28

The following SAS statements fit a linear regression model to the CrimeOH data set:

```

/*-- Linear Model --*/
proc cspatialreg data=mylib.CrimeOH;
    model crime = income hvalue / type=LINEAR;
run;

```

The “Model Fit Summary” table, shown in [Figure 13.2](#), lists several fit summary statistics for the model. By default, the CSPATIALREG procedure uses the Newton-Raphson optimization technique. The maximum log-likelihood value is shown, in addition to two information measures, Akaike’s information criterion (AIC) and Schwarz’s Bayesian information criterion (SBC). AIC or SBC can be used for model selection. For a set of candidate models, the model that has the smallest AIC or SBC is often preferred. In addition, the method that is used for covariance estimation is shown.

SBC	390.3215
Covariance Estimation	Hessian

The parameter estimates of the model and their standard errors are shown in [Figure 13.3](#). Based on the p -values, both Income and HValue are significant at the 0.05 level.

Figure 13.3 Parameter Estimates of the Linear Model

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	68.618863	4.588210	14.96	<.0001
income	1	-1.597304	0.323739	-4.93	<.0001
hvalue	1	-0.273931	0.099989	-2.74	0.0062
_sigma2	1	122.751696	24.799493	4.95	<.0001

The following statements fit a SAR model to the CrimeOH data set:

```

/*-- SAR Model --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
    model crime = income hvalue / type=SAR;
    spatialid sid;
run;

```

The NONORMALIZE option requests that the spatial weights matrix that is specified in the mylib.CrimeWmat data table be used “as is” rather than be row-standardized. The “Model Fit Summary” table, shown in [Figure 13.4](#), lists several fit summary statistics for the SAR model. For this model, the value of AIC is about 374.78—smaller than 382.75, which is the AIC value for the preceding linear model. Based on AIC, the SAR model is preferred.

Figure 13.4 Fit Summary Statistics for the SAR Model

The CSPATIALREG Procedure

Model Fit Summary	
Dependent Variable	crime
Number of Observations	49
Data Set	CRIMEOH
Spatial Weights	CRIMEWMAT
Model	SAR
Spatial ID Variable	sid
Log Likelihood	-182.36
Maximum Absolute Gradient	0.000192
Number of Iterations	16
Optimization Method	Newton-Raphson
AIC	374.7207
SBC	384.1798
Covariance Estimation	Hessian

The parameter estimates of the SAR model and their standard errors are shown in [Figure 13.5](#). According to the p -values, both Income and HValue are significant at the 0.05 level. In addition, the spatial autoregressive coefficient ρ is estimated to be about 0.431, with a p -value of 0.0005.

Figure 13.5 Parameter Estimates of the SAR Model

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	45.076368	7.870002	5.73	<.0001
income	1	-1.031514	0.328375	-3.14	0.0017
hvalue	1	-0.265923	0.088211	-3.01	0.0026
_rho	1	0.431032	0.123586	3.49	0.0005
_sigma2	1	95.470316	19.499458	4.90	<.0001

Unlike the previous SAR model, a spatial Durbin model (SDM) accounts for exogenous interaction effects by introducing additional spatially lagged regressors into the model. To fit an SDM, you need to combine the MODEL statement (with the TYPE=SAR option) and the SPATIALEFFECTS statement. The following statements fit an SDM :

```

/*-- SDM --*/
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
    model crime = income hvalue / type=SAR;
    spatialeffects income hvalue;
    spatialid sid;
run;

```

The fit summary statistics for the SDM are shown in [Figure 13.6](#). Parameter estimates are provided in [Figure 13.7](#).

Figure 13.6 Fit Summary Statistics for the SDM

The CSPATIALREG Procedure	
Model Fit Summary	
Dependent Variable	crime
Number of Observations	49
Data Set	CRIMEOH
Spatial Weights	CRIMEWMAT
Model	SDM
Spatial ID Variable	sid
Log Likelihood	-181.363
Maximum Absolute Gradient	0.000211
Number of Iterations	16
Optimization Method	Newton-Raphson
AIC	376.7269
SBC	389.9696
Covariance Estimation	Hessian

Figure 13.7 Parameter Estimates for the SDM

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	42.802410	13.923873	3.07	0.0021
income	1	-0.914200	0.336418	-2.72	0.0066
hvalue	1	-0.293746	0.088851	-3.31	0.0009
W_income	1	-0.519612	0.594739	-0.87	0.3823
W_hvalue	1	0.245718	0.176843	1.39	0.1647
_rho	1	0.426506	0.167485	2.55	0.0109
_sigma2	1	91.768262	18.904590	4.85	<.0001

The spatial autoregressive coefficient ρ is estimated to be 0.426 with a p -value of 0.0109 based on an asymptotic t test. This result seems to suggest that there is a significantly positive spatial dependence in the number of crimes.

In the CSPATIALREG procedure, the null hypothesis $H_0: \rho = 0$ can also be tested against the alternative $H_a: \rho \neq 0$ by using the likelihood ratio (LR) test, Lagrange multiplier (LM) test, and Wald test. For the LR test, the test statistic is equal to $-2(\mathcal{L}_{\text{linear}} - \mathcal{L}_{\text{SAR}}) = -2(-187.38 + 182.39) = 9.98$, where $\mathcal{L}_{\text{linear}}$ and $\mathcal{L}_{\text{SAR}}$ are the log likelihoods for the linear regression model and SAR model, respectively. The likelihood ratio test is significant at the 0.05 level, providing strong evidence of spatial dependence in the data.

Syntax: CSPATIALREG Procedure

The following statements are available in the CSPATIALREG procedure. Items within angle brackets (<>) or square brackets ([]) are optional.

```

PROC CSPATIALREG <options>;
  BOUNDS bound1 [ , bound2 ... ] ;
  BY variables ;
  CLASS variable <(options)> ... <variable <(options)>> </global-options>;
  DISPLAY <table-list> </options>;
  DISPLAYOUT table-spec-list </options>;
  INIT initialization1 < , initialization2 ... >;
  MODEL dependent-variable = regressors </options>;
  OUTPUT OUT=libref.data-table <options> <keyword <=name>> ... <keyword <=name>>>;
  RESTRICT restriction1 [ , restriction2 ... ] ;
  TEST equation1 < , equation2 ... > </test-options>;
  SPATIALEFFECTS <spatial-effect-regressors>;
  SPATIALID variable ;

```

You can specify only one MODEL statement. If you specify a BOUNDS, INIT, OUTPUT, RESTRICT, SPATIALEFFECTS, or TEST statement, it must appear after the MODEL statement. You can specify no more than one SPATIALEFFECTS statement. However, multiple BOUNDS, INIT, RESTRICT, and TEST statements are allowed.

Functional Summary

Table 13.1 summarizes the statements and options available in the CSPATIALREG procedure. The sections that follow provide detailed syntax information about each of these statements, beginning with the PROC CSPATIALREG statement. The remaining statements are covered in alphabetical order.

Table 13.1 Functional Summary

Description	Statement	Option
Data Table Options		
Specifies the input data table	PROC CSPATIALREG	DATA=
Specifies the spatial weights input data table	PROC CSPATIALREG	WMAT=
Suppresses normalization of the spatial weights	PROC CSPATIALREG	NONNORMALIZE
Writes estimates of $\mathbf{x}_i'\boldsymbol{\beta}$, predicted values, and residuals to an output data table	OUTPUT	OUT=

Outputs the residual	OUTPUT	RESID=
Outputs the expected value of the response variable	OUTPUT	PRED=
Outputs estimates of $\mathbf{x}'_i \boldsymbol{\beta}$	OUTPUT	XBETA=

PROC CSPATIALREG Statement

PROC CSPATIALREG *options* ;

You can specify the following *options* in the PROC CSPATIALREG statement.

Data Table Options

You must specify the following *option*:

DATA=*libref.data-table*

names the input data table for PROC CSPATIALREG to use. *libref.data-table* is a two-level name, where

libref refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about *libref*, see the section “Using CAS Sessions and CAS Engine Librefs” on page 638.

data-table specifies the name of the input data table.

This is the primary input data table, which contains dependent variables, explanatory variables, and so on.

For all models except a purely linear model, you must also specify the following *option*:

WMAT=libref.data-table

specifies the secondary spatial weights data table, which you can use to construct the spatial weights matrix **W**. *libref.data-table* is a two-level name, where *libref* refers to the library, and *data-table* specifies the name of the input data table. For more information about this two-level name, see the **DATA=** option and the section “Using CAS Sessions and CAS Engine Librefs” on page 638.

Loosely speaking, the entries of **W**, $w(s_i, s_j)$, define the amount of influence that a unit s_j has over a unit s_i . The entries $w(s_i, s_j)$ must be nonnegative and have zeros on the diagonal; that is, $w(s_i, s_j) \geq 0$ and $w(s_i, s_i) = 0$, where i and $j = 1, 2, \dots, n$ and n is the total number of spatial units in the data. Any nonzero diagonal elements $w(s_i, s_i)$ are replaced with 0. The spatial weights matrix can be asymmetric; that is, it is not necessary that $w(s_i, s_j) = w(s_j, s_i)$. For information about missing spatial weights in **W**, see the **NONORMALIZE** option.

The **W** matrix can take two different forms:

- You can provide a full spatial weights matrix. In this case, the data table that you specify in the **WMAT=** option has n rows and $n + 1$ columns and must have a column for spatial ID variable.
- You can specify the spatial weights matrix by using a compact form when appropriate. In this form, the number of observations in the data table that you specify in the **WMAT=** option should match the number of nonzero elements in the spatial weights matrix. Moreover, the number of columns in this data table should be three. The first two columns contain the row and column indices for nonzero entries in the spatial weights matrix, and the third column contains the nonzero entries in the spatial weights matrix. If you use the compact form for the spatial weights matrix, you must include a **SPATIALID** statement to match observations in the data tables that you specify in the **DATA=** and **WMAT=** options. For more information about the **SPATIALID** statement, see the section “**SPATIALID Statement**” on page 658. For more information about the compact representation of the spatial weights matrix, see the section “**Compact Representation of the Spatial Weights Matrix**” on page 672.

For all models except a purely linear model, you can also specify the following *option*:

NONORMALIZE

suppresses the row standardization of the spatial weights matrix that you specify in the **WMAT=** option. By default, the spatial weights matrix is row-standardized; that is, the spatial weights matrix has unit row sum. If you specify the **NONORMALIZE** option, spatial weights are used “as is” except for $w(s_i, s_i)$, which is always treated as 0. This implies that an entry $w(s_i, s_j)$ in the **W** matrix cannot be missing for $i \neq j$ if you specify this option. If you do not specify this option, missing spatial weights are replaced with zeros.

Approximation Control Option

For the SAR, SDM, SEM, SDEM, and CAR models, you can specify the following *options*:

APPROXIMATION=(*approx-options*)

specifies options that are related to approximating the Jacobian, as described in the section “[Approximations to the Jacobian](#)” on page 676. To invoke approximation, you must specify one or more of the following *approx-options*:

CHEBYSHEV | TAYLOR

specifies the approximation method. By default, Chebyshev approximation is used. The Taylor approximation is used only if you specify the TAYLOR option.

NMC=*number*

specifies a positive integer as the number of standard random normal draws for Monte Carlo simulation. By default, NMC=100.

ORDER=*number*

specifies a positive integer as the order of series in Taylor or Chebyshev approximation. If you specify Taylor approximation, ORDER=50 by default. If you specify Chebyshev approximation, ORDER=5 by default.

SEED=*number*

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator that is used for Monte Carlo simulation. Specifying a seed enables you to reproduce your analysis. By default, SEED=1.

Impact Estimation Control Option

For impact estimation, you can specify the following *options*:

IMPACT(*impacttest-option*)

specifies options that are related to impact estimation, as described in the section “[Impact Estimation](#)” on page 677. To invoke impact estimation, you must specify one or more of the following *impacttest-options*:

NMC=*number*

specifies a positive integer as the number of iterations for Monte Carlo simulation. By default, NMC=1000.

ORDER=*number*

specifies a positive integer as the highest order of the Neumann series for approximation. By default, ORDER=50.

SEED=*number*

specifies an integer seed in the range 1 to $2^{31} - 1$ for the random number generator that is used for Monte Carlo simulation. Specifying a seed enables you to reproduce your analysis. By default, SEED=1.

You can use the IMPACT option to summarize the average direct impacts, the average indirect impacts, and the average total impacts of explanatory variables in the model.

Printing Options

You can specify the following options in either the PROC CSPATIALREG statement or the MODEL statement:

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

NOPRINT

suppresses all printed output.

PRINTALL

requests all printing options.

PRINTINTERNALNAMES

prints internal names that are assigned to parameters.

PRINTTIMING

prints a timing report.

Estimation Control Options

You can specify the following options in either the PROC CSPATIALREG statement or the MODEL statement:

COVEST=HESSIAN | OP | QML

specifies the type of covariance matrix for the parameter estimates. You can specify the following types:

HESSIAN

specifies the covariance from the Hessian matrix.

OP

specifies the covariance from the outer product matrix.

QML

specifies the covariance from the outer product and Hessian matrices.

By default, COVEST=HESSIAN. The quasi-maximum-likelihood estimates are computed using COVEST=QML. For all models except the linear and SLX models, only COVEST=HESSIAN is supported.

TYPE=ALL | AUTO | CAR | LINEAR | SAC | SAR | SARMA | SEM | SMA

specifies the type of model to be fit. You can specify the following values:

ALL

fits all models.

AUTO

fits a subset of selected models.

CAR

fits a conditional autoregressive model.

LINEAR

fits a linear model.

SAC

fits a spatial autoregressive confused model.

SAR

fits a spatial autoregressive model.

SARMA	fits a spatial autoregressive moving average model.
SEM	fits a spatial error model.
SMA	fits a spatial moving average model.

By default, TYPE=SAR. For more information about the TYPE=ALL or TYPE=AUTO option, see the section “[Multiple Model Comparison](#)” on page 679.

If you specify covariates in the SPATIALEFFECT statement, then their spatial lag is added to the model. In that case, you can specify the following TYPE= option values to get the model that you want:

TYPE=CAR	fits the CAR2 model.
TYPE=LINEAR	fits the SLX model.
TYPE=SAC	fits the SDAC model.
TYPE=SAR	fits the SDM.
TYPE=SARMA	fits the SDARMA model.
TYPE=SEM	fits the SDEM.
TYPE=SMA	fits the SDMA model.

Optimization Control Options

PROC CSPATIALREG uses the nonlinear optimization (NLO) subsystem to perform nonlinear optimization tasks. You can specify the following *options* in either the PROC CSPATIALREG statement or the MODEL statement:

MAXFUNC=*i*

MAXFU=*i*

specifies the maximum number of function calls in the optimization process. By default, MAXFUNC=1000.

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually used can exceed the number of calls that you specify in this option.

MAXITER=*i*

MAXIT=*i*

specifies the maximum number of iterations in the optimization process. By default, MAXITER=200.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The default value is the largest floating-point double representation available on your computer. The time that you specify in this option is checked only once at the end of each iteration. Therefore, the actual run time can be much longer than *r*. The actual run time includes the remaining time that is needed to finish the iteration and the time that is needed to generate the output of the results.

METHOD=CONGRA | DBLDOG | NEWRAP | NONE | NRRIDG | QUANEW | TRUREG

specifies the iterative minimization method to use. You can specify the following methods:

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
NEWRAP	specifies the Newton-Raphson method.
NONE	specifies that optimization not be performed.
NRRIDG	specifies the Newton-Raphson ridge method.
QUANEW	specifies the quasi-Newton method.
TRUREG	specifies the trust region method.

By default, METHOD=NEWRAP.

BOUNDS Statement

BOUNDS *bound1* [, *bound2* ...] ;

The BOUNDS statement imposes simple boundary constraints on the parameter estimates. You can specify any number of BOUNDS statements.

Each *bound* is composed of parameter names, constants, and inequality operators as follows:

item operator item [*operator item* [*operator item* ...]]

Each *item* is a constant, a parameter name, or a list of parameter names. Each *operator* is <, >, <=, or >=. Parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)’), then you must use the internal name of the parameter to refer to that parameter in the BOUNDS statement. You can specify the PRINTINTERNALNAMES option in the PROC CSPATIALREG statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, the “Parameter Estimates” table includes an additional column that shows the internal name of each parameter.

You can use both the BOUNDS statement and the RESTRICT statement to impose boundary constraints. However, the BOUNDS statement provides a simpler syntax for specifying these kinds of constraints. For more information about the RESTRICT statement, see the section “[RESTRICT Statement](#)” on page 657.

The following BOUNDS statement constrains the estimates of the parameter for *z* to be negative, the parameters for *x1* through *x10* to be between 0 and 1, and the parameter for the spatial lag of *x1* to be less than 1:

```
bounds z < 0,
       0 < x1-x10 < 1,
       W_x1 < 1;
```

BY Statement

BY *variables* ;

You can use a BY statement in PROC CSPATIALREG to obtain separate analyses of observations in groups that are defined by the BY variables. When you use a BY statement, the primary input data table (specified in the DATA= option) should be sorted by the BY variables.

BY-statement processing is not supported when the CSPATIALREG procedure runs alongside the database or alongside the Hadoop Distributed File System (HDFS). These modes are used if the input data are stored in a database or HDFS and the grid host is the appliance that houses the data.

CLASS Statement

CLASS *variable* < (*options*) > . . . < *variable* < (*options*) > > < / *global-options* > ;

The CLASS statement names the classification variables to be used as explanatory variables in the analysis. You can list the response variable for binary models in the CLASS statement, but this is not required. [Table 13.2](#) summarizes the values that you can use for either an *option* or a *global-option*. The options are fully documented in the section “[CLASS Statement](#)” on page 56 in Chapter 4, “[Shared Concepts](#).”

Table 13.2 CLASS Statement Options

Option	Description
DESCENDING	Reverses the sort order
MISSING	Treats missing values as valid levels
ORDER=	Specifies the sort order for the levels
PARAM=	Specifies the parameterization of the variable
REF=	Specifies the reference level of the variable
SPLIT	Splits levels of CLASS variables into independent effects

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE

statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “ODS Table Names” on page 686. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetted for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

- | | |
|------------------|---|
| <i>key=value</i> | specifies <i>key</i> as the ODS table name, path, or partial pathname, and specifies <i>value</i> as the output table name. |
| <i>key</i> | specifies <i>key</i> as the ODS table name and also as the output table name. |

The ODS table names that you can specify are listed in the section “[ODS Table Names](#)” on page 686. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

INIT Statement

INIT *initialization1* < , *initialization2* ... > ;

The INIT statement sets initial values for parameters in the optimization.

Each *initialization* is written as a parameter or parameter list, followed by an optional equal sign (=), followed by a number:

parameter <=> *number*

Parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)’), then you must use the internal name of the parameter to refer to that parameter in the INIT statement. You can specify the PRINTINTERNALNAMES option in the PROC CSPATIALREG statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, the “Parameter Estimates” table includes an additional column that shows the internal name of each parameter.

For more information about how parameters are named in the INIT statement, see the section “[Parameter Naming Conventions for RESTRICT, TEST, BOUNDS, and INIT Statements](#)” on page 680.

MODEL Statement

MODEL *dependent-variable* = *regressors* </ options> ;

The MODEL statement specifies the *dependent-variable* and independent covariates (*regressors*) for the regression model. If you specify no *regressors*, PROC CSPATIALREG fits a model that contains only an intercept. The *dependent-variable* is treated as a continuous variable in the primary input data table (specified in the DATA= option). Models in PROC CSPATIALREG do not allow missing values. If there are missing values, an error message is returned.

You can specify only one MODEL statement. You can specify the following *options* after a slash (/):

NOINT

suppresses the intercept parameter.

TYPE=ALL | AUTO | CAR | LINEAR | SAC | SAR | SARMA | SEM | SMA

specifies the type of model to be fit. If you specify this option in both the MODEL statement and the PROC CSPATIALREG statement, the MODEL statement overrides the PROC CSPATIALREG statement. You can specify the following values:

ALL	fits all models.
AUTO	fits a subset of selected models.
CAR	fits a conditional autoregressive model.
LINEAR	fits a linear model.
SAC	fits a spatial autoregressive confused model.
SAR	fits a spatial autoregressive model.
SARMA	fits a spatial autoregressive moving average model.
SEM	fits a spatial error model.
SMA	fits a spatial moving average model.

By default, TYPE=SAR. For more information about the TYPE=ALL or TYPE=AUTO option, see the section “[Multiple Model Comparison](#)” on page 679.

If you specify covariates in the SPATIALEFFECT statement, then their spatial lag is added to the model. In that case, you can specify the following TYPE= option values to get the model that you want:

TYPE=CAR	fits the CAR2 model.
TYPE=LINEAR	fits the SLX model.
TYPE=SAC	fits the SDAC model.
TYPE=SAR	fits the SDM.
TYPE=SARMA	fits the SDARMA model.
TYPE=SEM	fits the SDEM.
TYPE=SMA	fits the SDMA model.

Printing Options

You can specify the following options in either the PROC CSPATIALREG statement or the MODEL statement. If you specify these options in both the PROC CSPATIALREG and MODEL statements, the MODEL statement overrides the PROC CSPATIALREG statement.

CORRB

prints the correlation matrix of the parameter estimates.

COVB

prints the covariance matrix of the parameter estimates.

NOPRINT

suppresses all printed output.

PRINTALL

prints all available output.

Optimization Control Options

You can specify the following options in either the PROC CSPATIALREG statement or the MODEL statement. If you specify these options in both the PROC CSPATIALREG and MODEL statements, the MODEL statement overrides the PROC CSPATIALREG statement.

MAXFUNC=*i*

MAXFU=*i*

specifies the maximum number of function calls in the optimization process. By default, MAXFUNC=1000.

The optimization can terminate only after completing a full iteration. Therefore, the number of function calls that are actually used can exceed the number of calls that you specify in this option.

MAXITER=*i*

MAXIT=*i*

specifies the maximum number of iterations in the optimization process. By default, MAXITER=200.

MAXTIME=*r*

specifies an upper limit of *r* seconds of CPU time for the optimization process. The default value is the largest floating-point double representation available on your computer. The time that you specify in this option is checked only once at the end of each iteration. Therefore, the actual run time can be much longer than *r*. The actual run time includes the remaining time that is needed to finish the iteration and the time that is needed to generate the output of the results.

METHOD=CONGRA | DBLDOG | NEWRAP | NONE | NRRIDG | QUANEW | TRUREG

specifies the iterative minimization method to use. You can specify the following methods:

CONGRA	specifies the conjugate-gradient method.
DBLDOG	specifies the double-dogleg method.
NEWRAP	specifies the Newton-Raphson method.
NONE	specifies that optimization not be performed.

NRRIDG	specifies the Newton-Raphson ridge method.
QUANEW	specifies the quasi-Newton method.
TRUREG	specifies the trust region method.

By default, METHOD=NEWRAP.

OUTPUT Statement

```
OUTPUT OUT=libref.data-table
           < options >
           < keyword < =name > > . . . < keyword < =name > > ;
```

The OUTPUT statement creates a data table that contains observationwise statistics that PROC CSPATIALREG computes after fitting the model. These observationwise statistics include the estimates of $\mathbf{x}_i' \boldsymbol{\beta}$, the expected value of the response variable, and the residual. In order to avoid data duplication for large data tables, the variables in the input data table are *not* included in the output data table unless you specify them in the COPYVAR= option.

You can specify only one OUTPUT statement. You must specify the following option:

OUT=*libref.data-table*
 names the output data table for PROC CSPATIALREG to use. You must specify this option before any other options. *libref.data-table* is a two-level name, where

<i>libref</i>	refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to where the data table is to be stored, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about <i>libref</i> , see the section “Using CAS Sessions and CAS Engine Librefs” on page 638.
<i>data-table</i>	specifies the name of the output data table.

You can also specify the following *options*:

COPYVAR=*variable*

COPYVARS=*variables*

transfers one or more variables from the primary input data table to the output data table.

PRED=*name*

MEAN=*name*

assigns a name to the variable that contains the predicted value of the response variable.

RESID=*name*

RESIDUAL=*name*

assigns a name to the variable that contains the residuals (that is, the difference between the observed and predicted values of the response variable).

XBETA=*name*

names the variable that contains estimates of $\mathbf{x}_i' \boldsymbol{\beta}$.

RESTRICT Statement

RESTRICT *restriction1* [, *restriction2* ...] ;

The RESTRICT statement imposes linear restrictions on the parameter estimates. You can specify any number of RESTRICT statements.

Each *restriction* is written as an expression, followed by an equality operator (=) or an inequality operator (<, >, <=, >=), followed by a second expression:

expression operator expression

The *operator* can be =, <, >, <=, or >=.

Restriction expressions can be composed of parameter names; constants; and the operators times (*), plus (+), and minus (–). The restriction expressions must be a linear function of the parameters.

Parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)’), then you must use the internal name of the parameter to refer to that parameter in the RESTRICT statement. You can specify the PRINTINTERNALNAMES option in the PROC CSPATIALREG statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, the “Parameter Estimates” table includes an additional column that shows the internal name of each parameter.

For more information about how parameters are named in the RESTRICT statement, see the section “[Parameter Naming Conventions for RESTRICT, TEST, BOUNDS, and INIT Statements](#)” on page 680.

Lagrange multipliers are reported in the “Parameter Estimates” table for all the active linear constraints. They are identified by the names Restrict1, Restrict2, and so on. The *p*-values of these Lagrange multipliers are computed using a beta distribution (LaMotte 1994). Nonactive (nonbinding) restrictions have no effect on the estimation results and are not noted in the output.

For example, the following RESTRICT statement constrains the spatial autoregressive coefficient ρ to 0, which removes endogenous interaction effects:

```
restrict _rho = 0;
```

SPATIALEFFECTS Statement

SPATIALEFFECTS < *spatial-effect-regressors* > < /*options* > ;

The SPATIALEFFECTS statement enables you to specify covariates (such as *Z*) whose spatial lag, *WZ*, is to be added to the model.

PROC CSPATIALREG adds the spatially weighted *spatial-effect-regressors* to regressors that you specify in the MODEL statement. For example, if you specify q variables $z_1, \dots, z_q$ in the SPATIALEFFECTS statement, then each of q spatially weighted variables, as represented by each column of *WZ*, has a parameter to be included in the regression. Here, *WZ* denotes the matrix product of *W* and *Z*. In addition, *Z* is the design matrix that is formed by the q variables $z_1, \dots, z_q$. The spatial weights matrix *W* comes from the data table that you specify in the WMAT= option. The “Parameter Estimates” table in the displayed output shows the estimates for spatially weighted *spatial-effect-regressors*; they are labeled with the prefix “W_”. For example, if you specify *z* (a variable in your primary data table) as a *model-spatial-effect-regressor*, then the “Parameter Estimates” table labels the corresponding parameter estimate “W_*z*”.

SPATIALID Statement

SPATIALID *variable* ;

The SPATIALID statement specifies a variable that identifies a spatial unit for each observation in the two data tables that you specify in the DATA= and WMAT= options in the PROC CSPATIALREG statement. The variable that you specify in the SPATIALID statement is also used to match the rows and columns in the spatial weights matrix. Only one SPATIALID statement and one spatial ID *variable* are allowed. For all models except a purely linear regression model without an SLX effect, you need a SPATIALID statement in order to specify a spatial ID *variable* for the purpose of matching observations in two data tables that you specify in the DATA= and WMAT= options. The values of the spatial ID *variable* in either the DATA= or WMAT= data table cannot be missing.

The *variable* in the SPATIALID statement can be either numeric or character. However, the type of spatial ID *variable* in the two data tables that you specify in the DATA= and WMAT= options must be the same. When the spatial ID *variable* is numeric, it needs to be integer-valued. If you specify a number that is not an integer, PROC CSPATIALREG uses the integer part of that number for matching.

TEST Statement

< *label* : > **TEST** < '*string*' > *equation1* < , *equation2* . . . > / < *test-options* > ;

The TEST statement performs Wald, Lagrange multiplier, and likelihood ratio tests of linear hypotheses about the parameters that you specify in the preceding MODEL statement.

You can add a label (which is printed in the output) to a TEST statement in two ways: add an unquoted *label* followed by a colon before the TEST keyword, or add a quoted *string* after the TEST keyword. The unquoted *label* cannot contain spaces. If you include both an unquoted *label* and a quoted *string*, PROC CSPATIALREG uses the unquoted *label*. If you specify neither an unquoted *label* nor a quoted *string*, PROC CSPATIALREG automatically labels the tests.

Each *equation* specifies a linear hypothesis to be tested and consists of regression parameter names and relational operators. The regression parameter names are as shown in the Parameter column of the “Parameter Estimates” table. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)’), then you must use the internal name of the parameter to refer to that parameter in the TEST statement. You can specify the PRINTINTERNALNAMES option in the PROC CSPATIALREG statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, the “Parameter Estimates” table includes an additional column that shows the internal name of each parameter.

For more information about how parameters are named in the TEST statement, see the section “[Parameter Naming Conventions for RESTRICT, TEST, BOUNDS, and INIT Statements](#)” on page 680. Only linear equality restrictions and tests are permitted in PROC CSPATIALREG. Test *equations* can consist only of algebraic operations that involve the addition symbol (+), subtraction symbol (-), and multiplication symbol (*).

All hypotheses in a TEST statement are tested jointly.

You can specify the following options after the slash (/):

ALL

requests the Wald, Lagrange multiplier, and likelihood ratio tests.

LM

requests the Lagrange multiplier test.

LR

requests the likelihood ratio test.

WALD

requests the Wald test.

The following statements illustrate the use of the TEST statement:

```
proc cspatialreg data=mylib.dat;
  model y = x1 x2 x3/type=LINEAR;
  test x1 = 0, x2 * .5 + 2 * x3 = 0/ALL;
  test_int: test intercept = 0, x3 = 0/LR;
run;
```

The first test investigates the joint hypothesis that $\beta_1 = 0$ and $0.5\beta_2 + 2\beta_3 = 0$.

The TEST statement accepts labels that are reproduced in the printed output. TEST statements can be labeled in two ways: a TEST statement can be preceded by a label followed by a colon, or the keyword TEST can be followed by a quoted string. If both are present, PROC CSPATIALREG uses the label preceding the colon. If no label is specified, PROC CSPATIALREG automatically labels the tests.

Details: CSPATIALREG Procedure

Missing Values

Missing values can occur in both the primary data table (which you specify in the `DATA=` option) and the secondary spatial weights data table (which you specify in the `WMAT=` option). The CSPATIALREG procedure does not allow missing values in the primary input data table. If any observation in the primary input data table has a missing value for one or more of the regressors or the dependent variable, PROC CSPATIALREG will not fit the model. If any observation in the primary data table has a missing value for the spatial ID variable when you specify the `SPATIALID` statement, PROC CSPATIALREG will not fit the model. In such cases, you get an error message.

For the secondary spatial weights data table, a missing value for the spatial ID variable is not allowed when you specify the `SPATIALID` statement. Moreover, missing spatial weights are not allowed if you specify the `NONNORMALIZE` option. In these cases, PROC CSPATIALREG issues an error message and skips the model fitting.

Spatial Autoregressive Models

The spatial autoregressive (SAR) model is useful for incorporating spatial dependence in the dependent variable—that is, the endogenous interaction effect. Let y_i denote the observation that is associated with a spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let an $n \times n$ matrix $\mathbf{W}$ with nonnegative elements be a spatial weights matrix and let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded for the spatial unit s_i . You can formulate the SAR model as

$$y_i = \rho \sum_{j=1}^n W_{ij} y_j + \mathbf{x}_i' \boldsymbol{\beta} + \epsilon_i$$

where $i = 1, 2, \dots, n$, ρ is the spatial autoregressive coefficient, $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector, W_{ij} is the (i, j) th element of the matrix $\mathbf{W}$ subject to $W_{ii} = 0$, and the error term ϵ_i that is related to the spatial unit s_i is assumed to follow $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$ for $i = 1, 2, \dots, n$.

The SAR model is often described in vector form as

$$\mathbf{y} = \rho \mathbf{W} \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$, and $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$.

The standard estimator for the SAR model is the maximum likelihood estimator (MLE). For the SAR model, the log-likelihood function is (Anselin 2001)

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2\sigma^2} + \ln |\mathbf{A}|$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}$, $\mathbf{I}_n$ is an $n \times n$ identity matrix, and $|\mathbf{A}|$ denotes the determinant of $\mathbf{A}$.

You can derive the gradients as follows:

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} &= \frac{\mathbf{X}'(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2} \\ \frac{\partial \mathcal{L}}{\partial \rho} &= \frac{1}{\sigma^2} \mathbf{y}'\mathbf{W}'(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta}) - \text{tr}(\mathbf{A}^{-1}\mathbf{W}) \\ \frac{\partial \mathcal{L}}{\partial \sigma^2} &= -\frac{n}{2\sigma^2} + \frac{(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2\sigma^4}\end{aligned}$$

For the $n \times n$ matrix $\mathbf{A}$, $\text{tr}(\mathbf{A}) = \sum_{i=1}^n a_{ii}$, where a_{ii} is the i th diagonal element of $\mathbf{A}$.

A SAR model does not account for exogenous interaction effects. In practice, the value of the dependent variable y for a spatial unit might also be affected by some independent explanatory variables of other spatial units. In such a case, you can use the spatial Durbin model instead.

Spatial Durbin Models

Unlike a SAR model, a spatial Durbin model (SDM) can account for exogenous interaction effects in addition to the endogenous interaction effects. Let y_i denote the observation that is associated with a spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be an $n \times n$ spatial weights matrix of your choice. Further assume that $\mathbf{x}_i$ is a $p \times 1$ vector that denotes values of p regressors that are recorded for the spatial unit s_i and assume that $\mathbf{z}_i$ is a $q \times 1$ vector that denotes values of q regressors that are measured at unit s_i .

The SDM can be described in vector form as (LeSage and Pace 2009)

$$\mathbf{y} = \rho \mathbf{W}\mathbf{y} + \mathbf{X}\boldsymbol{\beta} + \mathbf{WZ}\boldsymbol{\theta} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$, $\mathbf{Z}$ is an $n \times q$ matrix where each row consists of $\mathbf{z}_i'$, and $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$ are $p \times 1$ and $q \times 1$ parameter vectors, respectively.

By letting $\widetilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{WZ}]$ and $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, you can rewrite the SDM as

$$\mathbf{y} = \rho \mathbf{W}\mathbf{y} + \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}} + \boldsymbol{\epsilon}$$

The log-likelihood function for the SDM is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})'(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})}{2\sigma^2} + \ln |\mathbf{A}|$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}$.

For the SDM, the gradients are

$$\begin{aligned}\frac{\partial \mathcal{L}}{\partial \widetilde{\boldsymbol{\beta}}} &= \frac{\widetilde{\mathbf{X}}'(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})}{\sigma^2} \\ \frac{\partial \mathcal{L}}{\partial \rho} &= \frac{1}{\sigma^2} \mathbf{y}'\mathbf{W}'(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}}) - \text{tr}(\mathbf{A}^{-1}\mathbf{W}) \\ \frac{\partial \mathcal{L}}{\partial \sigma^2} &= -\frac{n}{2\sigma^2} + \frac{(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})'(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})}{2\sigma^4}\end{aligned}$$

Both the SDM and the SAR model account for endogenous interaction effects. However, in some cases there might be an interaction among error terms. In such cases, you might consider a spatial error model, which addresses spatial interaction among error terms.

Spatial Error Models

The spatial error model (SEM) accounts for spatial dependence in the error terms rather than in the dependent variable. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be an $n \times n$ spatial weights matrix. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i .

The SEM can be described in vector form by using the following two-stage formulation (LeSage and Pace 2009),

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}$$

$$\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

The log-likelihood function for the SEM is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^2} + \ln |\mathbf{B}|$$

where $\mathbf{B} = \mathbf{I}_n - \lambda \mathbf{W}$.

For the SEM, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{(\mathbf{B}\mathbf{X})' [\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \frac{1}{\sigma^2} [\mathbf{W}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})] - \text{tr}(\mathbf{B}^{-1}\mathbf{W})$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^4}$$

In addition to the interaction effects among error terms, you might also want to include exogenous interaction effects in the model. In such cases, you need to consider a spatial Durbin error model.

Spatial Durbin Error Models

The spatial Durbin error model (SDEM) accounts for spatial dependence among the error terms and the exogenous interaction effect. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be an $n \times n$ spatial weights matrix. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i , and let $\mathbf{z}_i$ be a $q \times 1$ vector that denotes values of q regressors that are measured at unit s_i .

The SDEM can be described in vector form by using the following two-stage formulation (LeSage and Pace 2009),

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{W}\mathbf{Z}\boldsymbol{\theta} + \mathbf{u}$$

$$\mathbf{u} = \lambda \mathbf{W}\mathbf{u} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$, $\mathbf{Z}$ is an $n \times q$ matrix where each row consists of $\mathbf{z}_i'$, and $\boldsymbol{\beta}$ and $\boldsymbol{\theta}$ are $p \times 1$ and $q \times 1$ parameter vectors, respectively.

By letting $\widetilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{WZ}]$ and $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, you can rewrite the SDEM as

$$\mathbf{y} = \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}} + \mathbf{B}^{-1}\boldsymbol{\epsilon}$$

where $\mathbf{B} = \mathbf{I}_n - \lambda\mathbf{W}$.

The log-likelihood function for the SDEM is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^2} + \ln |\mathbf{B}|$$

For the SDEM, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \widetilde{\boldsymbol{\beta}}} = \frac{(\mathbf{B}\widetilde{\mathbf{X}})' [\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \frac{1}{\sigma^2} [\mathbf{W}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})] - \text{tr}(\mathbf{B}^{-1}\mathbf{W})$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^4}$$

Spatial Moving Average Models

The spatial moving average (SMA) model accounts for spatial dependence among the error terms; thus it is similar to the SEM model but with a different autocorrelation structure. The SMA model is used for modeling local autocorrelation. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be an $n \times n$ spatial weights matrix, and let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i .

The SMA model can be described in vector form by using the following two-stage formulation,

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{u}$$

$$\mathbf{u} = (\mathbf{I}_n - \lambda\mathbf{W})\boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix that has $\mathbf{x}_i'$ in each row, $\mathbf{Z}$ is an $n \times q$ matrix that has $\mathbf{z}_i'$ in each row, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

The log-likelihood function for the SMA model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^2} - \ln |\mathbf{B}|$$

where $\mathbf{B} = \mathbf{I}_n - \lambda\mathbf{W}$.

For the SMA model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{(\mathbf{B}^{-1}\mathbf{X})' [\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = -\frac{1}{\sigma^2} [\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1}\mathbf{W}] [\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})] + \text{tr}(\mathbf{B}^{-1}\mathbf{W})$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1}(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^4}$$

Spatial Durbin Moving Average Models

The term spatial Durbin moving average (SDMA) model is used to refer to the SMA model that accommodates exogenous interaction effects. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be an $n \times n$ spatial weights matrix. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i , and let $\mathbf{z}_i$ be a $q \times 1$ vector that denotes values of q covariates that are measured at unit s_i .

The SDMA model can be described in vector form as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{WZ}\boldsymbol{\theta} + (\mathbf{I}_n - \lambda\mathbf{W})\boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$; $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$; $\mathbf{X}$ and $\mathbf{Z}$ are $n \times p$ and $n \times q$ matrices, where each row consists of $\mathbf{x}_i'$ and $\mathbf{z}_i'$, respectively; $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector; and $\boldsymbol{\theta}$ is a $q \times 1$ parameter vector.

By letting $\widetilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{WZ}]$ and $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, the SDMA model can be written as

$$\mathbf{y} = \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}} + \mathbf{B}\boldsymbol{\epsilon}$$

The log-likelihood function for the SDMA model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^2} - \ln |\mathbf{B}|$$

where $\mathbf{B} = \mathbf{I}_n - \lambda\mathbf{W}$ and $|\mathbf{B}|$ denotes the determinant of matrix $\mathbf{B}$.

For the SDMA model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \widetilde{\boldsymbol{\beta}}} = \frac{(\mathbf{B}^{-1}\widetilde{\mathbf{X}})' [\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = -\frac{1}{\sigma^2} [\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1}\mathbf{W}] [\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})] + \text{tr}(\mathbf{B}^{-1}\mathbf{W})$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1}(\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^4}$$

Spatial Autoregressive Moving Average Models

The spatial autoregressive moving average (SARMA) model, like the SMA model, can account for spatial dependence among the error terms. In addition, the SARMA model enables you to account for spatial dependence in the dependent variable, as the SAR model does. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let the $n \times n$ matrices $\mathbf{W}_1$ and $\mathbf{W}_2$ be two spatial weights matrices that contain nonnegative elements. In practice, $\mathbf{W}_1$ and $\mathbf{W}_2$ can be identical. Further, it is assumed that $\mathbf{x}_i$ is a $p \times 1$ vector that denotes values of p covariates that are recorded at unit s_i .

The SARMA model can be described in vector form by using the following two-stage formulation (LeSage and Pace 2009),

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \mathbf{u}$$

$$\mathbf{u} = (\mathbf{I}_n - \lambda \mathbf{W}_2) \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix that consists of $\mathbf{x}_i'$ in each row, $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector, and $\mathbf{I}_n$ is an $n \times n$ identity matrix.

The log-likelihood function for the SARMA model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^2} + \ln |\mathbf{A}| - \ln |\mathbf{B}|$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}_1$, $\mathbf{B} = \mathbf{I}_n - \lambda \mathbf{W}_2$, and $|\cdot|$ denotes the matrix determinant operator.

For the SARMA model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{(\mathbf{B}^{-1} \mathbf{X})' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \rho} = \frac{(\mathbf{B}^{-1} \mathbf{W}_1 \mathbf{y})' \mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2} - \text{tr}(\mathbf{A}^{-1} \mathbf{W}_1)$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = -\frac{1}{\sigma^2} [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1} \mathbf{W}_2] [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})] + \text{tr}(\mathbf{B}^{-1} \mathbf{W}_2)$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^4}$$

Spatial Durbin Autoregressive Moving Average Models

You can also accommodate exogenous interaction effects in the SARMA model. The term spatial Durbin autoregressive moving average (SDARMA) model is used to refer to such an extension of the SARMA model. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}_1$ and $\mathbf{W}_2$ be two spatial weights matrices. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i , and let $\mathbf{z}_i$ be a $q \times 1$ vector that denotes values of q regressors that are measured at unit s_i .

The SDARMA model can be described in vector form by using the following two-stage formulation,

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \mathbf{W}_1 \mathbf{Z} \boldsymbol{\theta} + \mathbf{u}$$

$$\mathbf{u} = (\mathbf{I}_n - \lambda \mathbf{W}_2) \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix that has $\mathbf{x}_i'$ in each row, $\mathbf{Z}$ is an $n \times q$ matrix that has $\mathbf{z}_i'$ in each row, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

By letting $\widetilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{W}_1 \mathbf{Z}]$ and $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, the SDARMA model can be written as

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \widetilde{\mathbf{X}} \widetilde{\boldsymbol{\beta}} + (\mathbf{I}_n - \lambda \mathbf{W}_2) \boldsymbol{\epsilon}$$

The log-likelihood function for the SDARMA model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^2} + \ln |\mathbf{A}| - \ln |\mathbf{B}|$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}_1$ and $\mathbf{B} = \mathbf{I}_n - \lambda \mathbf{W}_2$.

For the SDARMA model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \widetilde{\boldsymbol{\beta}}} = \frac{(\mathbf{B}^{-1} \widetilde{\mathbf{X}})' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \rho} = \frac{(\mathbf{B}^{-1} \mathbf{W}_1 \mathbf{y})' \mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})}{\sigma^2} - \text{tr}(\mathbf{A}^{-1} \mathbf{W}_1)$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = -\frac{1}{\sigma^2} [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1} \mathbf{W}_2] [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})] + \text{tr}(\mathbf{B}^{-1} \mathbf{W}_2)$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}^{-1}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^4}$$

Spatial Autoregressive Confused Models

The spatial autoregressive confused (SAC) model, like the SARMA model, can accommodate spatial dependence in both the dependent variable and error terms. However, the covariance structure for the error terms in a SAC model is different from that of the SARMA model. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}_1$ and $\mathbf{W}_2$ be two spatial weights matrices, and let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i .

The SAC model can be described in vector form by using the following two-stage formulation (LeSage and Pace 2009),

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \mathbf{u}$$

$$\mathbf{u} = \lambda \mathbf{W}_2 \mathbf{u} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix that has $\mathbf{x}_i'$ in each row, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

The log-likelihood function for the SAC model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^2} + \ln |\mathbf{A}| + \ln |\mathbf{B}|$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}_1$ and $\mathbf{B} = \mathbf{I}_n - \lambda \mathbf{W}_2$.

For the SAC model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{(\mathbf{B}\mathbf{X})' [\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \rho} = \frac{(\mathbf{B}\mathbf{W}_1 \mathbf{y})' \mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2} - \text{tr}(\mathbf{A}^{-1} \mathbf{W}_1)$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \frac{1}{\sigma^2} [\mathbf{W}_2(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})] - \text{tr}(\mathbf{B}^{-1} \mathbf{W}_2)$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \mathbf{X}\boldsymbol{\beta})]}{2\sigma^4}$$

Spatial Durbin Autoregressive Confused Models

The SAC model can be extended to account for exogenous interaction effects. The term spatial Durbin autoregressive confused (SDAC) model is used to refer to such an extension of the SAC model. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}_1$ and $\mathbf{W}_2$ be two spatial weights matrices. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors that are recorded at unit s_i , and assume that $\mathbf{z}_i$ is a $q \times 1$ vector that denotes values of q regressors that are measured at unit s_i .

The SDAC model can be described in vector form by using the following two-stage formulation,

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \mathbf{W}_1 \mathbf{Z} \boldsymbol{\theta} + \mathbf{u}$$

$$\mathbf{u} = (\mathbf{I}_n - \lambda \mathbf{W}_2)^{-1} \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix that has $\mathbf{x}_i'$ in each row, $\mathbf{Z}$ is an $n \times q$ matrix that has $\mathbf{z}_i'$ in each row, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

By letting $\widetilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{W}_1 \mathbf{Z}]$ and $\widetilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, the SDAC model can be rewritten as

$$\mathbf{y} = \rho \mathbf{W}_1 \mathbf{y} + \widetilde{\mathbf{X}} \widetilde{\boldsymbol{\beta}} + (\mathbf{I}_n - \lambda \mathbf{W}_2)^{-1} \boldsymbol{\epsilon}$$

The log-likelihood function for the SDAC model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{[\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^2} + \ln |\mathbf{A}| + \ln |\mathbf{B}|$$

For the SDAC model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \widetilde{\boldsymbol{\beta}}} = \frac{(\mathbf{B}\widetilde{\mathbf{X}})' [\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \rho} = \frac{(\mathbf{B}\mathbf{W}_1 \mathbf{y})' \mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})}{\sigma^2} - \text{tr}(\mathbf{A}^{-1} \mathbf{W}_1)$$

$$\frac{\partial \mathcal{L}}{\partial \lambda} = \frac{1}{\sigma^2} [\mathbf{W}_2(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})] - \text{tr}(\mathbf{B}^{-1} \mathbf{W}_2)$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{[\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]' [\mathbf{B}(\mathbf{A}\mathbf{y} - \widetilde{\mathbf{X}}\widetilde{\boldsymbol{\beta}})]}{2\sigma^4}$$

Linear Regression Models

You can also fit a linear regression model in PROC CSPATIALREG. In this case, let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$, and let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors recorded at unit s_i .

You can describe the linear regression model in vector form as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, and $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$.

The log-likelihood function for the linear regression model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2\sigma^2}$$

For the linear regression model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{\mathbf{X}'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2\sigma^4}$$

The Hessians take the following forms:

$$\frac{\partial^2 \mathcal{L}}{\partial \boldsymbol{\beta} \partial \boldsymbol{\beta}'} = -\frac{\mathbf{X}'\mathbf{X}}{\sigma^2}$$

$$\frac{\partial^2 \mathcal{L}}{\partial \boldsymbol{\beta} \partial \sigma^2} = -\frac{\mathbf{X}'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^4}$$

$$\frac{\partial^2 \mathcal{L}}{\partial \sigma^4} = \frac{n}{2\sigma^4} - \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})'(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^6}$$

Spatial Lag of X Models

The spatial lag of X (SLX) model assumes no endogenous interaction effects or spatial dependence in the error terms. Instead, it incorporates only exogenous interaction effects into the linear regression model. Let y_i denote the observation that is associated with the spatial unit s_i for $i = 1, 2, \dots, n$. For these spatial units, let $\mathbf{W}$ be a spatial weights matrix. Further, let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors recorded at unit s_i , and let $\mathbf{z}_i$ be a $q \times 1$ vector that denotes values of q regressors measured at unit s_i .

The SLX model can be described in vector form as

$$\mathbf{y} = \mathbf{X}\boldsymbol{\beta} + \mathbf{WZ}\boldsymbol{\theta} + \boldsymbol{\epsilon}$$

where $\mathbf{y} = (y_1, y_2, \dots, y_n)'$, $\boldsymbol{\epsilon} = (\epsilon_1, \epsilon_2, \dots, \epsilon_n)'$ with $\epsilon_i \stackrel{\text{iid}}{\sim} N(0, \sigma^2)$, $\mathbf{X}$ is an $n \times p$ matrix where each row consists of $\mathbf{x}_i'$, $\mathbf{Z}$ is an $n \times q$ matrix where each row consists of $\mathbf{z}_i'$, and $\boldsymbol{\beta}$ is a $p \times 1$ parameter vector.

By letting $\tilde{\mathbf{X}} = [\mathbf{X} \ \mathbf{WZ}]$ and $\tilde{\boldsymbol{\beta}} = (\boldsymbol{\beta}' \ \boldsymbol{\theta}')'$, you can rewrite the SLX model as

$$\mathbf{y} = \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}} + \boldsymbol{\epsilon}$$

The log-likelihood function for the SLX model is

$$\mathcal{L} = -\frac{n}{2} \ln(2\pi\sigma^2) - \frac{(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})'(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})}{2\sigma^2}$$

For the SLX model, the gradients are

$$\frac{\partial \mathcal{L}}{\partial \tilde{\boldsymbol{\beta}}} = \frac{(\tilde{\mathbf{X}})'(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})'(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})}{2\sigma^4}$$

The Hessians take the following forms:

$$\frac{\partial^2 \mathcal{L}}{\partial \tilde{\boldsymbol{\beta}} \partial \tilde{\boldsymbol{\beta}}'} = -\frac{\tilde{\mathbf{X}}'\tilde{\mathbf{X}}}{\sigma^2}$$

$$\frac{\partial^2 \mathcal{L}}{\partial \tilde{\boldsymbol{\beta}} \partial \sigma^2} = -\frac{\tilde{\mathbf{X}}'(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})}{\sigma^4}$$

$$\frac{\partial^2 \mathcal{L}}{\partial \sigma^4} = \frac{n}{2\sigma^4} - \frac{(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})'(\mathbf{y} - \tilde{\mathbf{X}}\tilde{\boldsymbol{\beta}})}{\sigma^6}$$

Conditional Autoregressive Models

Let y_i denote the observation that is associated with a spatial unit s_i for $i = 1, 2, \dots, n$, and let $\mathbf{x}_i$ be a $p \times 1$ vector that denotes values of p regressors recorded at unit s_i .

The conditional autoregressive (CAR) model is defined by the set of full conditional distributions as

$$y_i | \mathbf{Y}_{(i)} \sim N \left(\mathbf{x}_i' \boldsymbol{\beta} + \sum_{j=1}^n C_{ij} (y_j - \mathbf{x}_j' \boldsymbol{\beta}), \sigma_i^2 \right)$$

where $\mathbf{Y}_{(i)} = (y_1, y_2, \dots, y_{i-1}, y_{i+1}, \dots, y_n)'$ and $\mathbf{C}$ is an $n \times n$ matrix whose (i, j) th element is C_{ij} .

Denote $\mathbf{M} = \text{diagonal}(\sigma_1^2, \sigma_2^2, \dots, \sigma_n^2)$. Under the conditions that $\mathbf{M}^{-1}\mathbf{C}$ is symmetric and $\mathbf{M}^{-1}(\mathbf{I}_n - \mathbf{C})$ is positive definite, the joint distribution of $\mathbf{y}$ is well defined as

$$\mathbf{y} \sim N(\mathbf{X}\boldsymbol{\beta}, \boldsymbol{\Sigma})$$

where $\mathbf{X}$ is an $n \times p$ matrix in which each row consists of $\mathbf{x}_i'$ and $\boldsymbol{\Sigma} = (\mathbf{I}_n - \mathbf{C})^{-1}\mathbf{M}$.

The log-likelihood function for the CAR model takes the form

$$\mathcal{L} = -\frac{n}{2} \ln 2\pi - \frac{1}{2} \ln |\boldsymbol{\Sigma}| - \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})' \boldsymbol{\Sigma}^{-1} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2}$$

Often, it is considered that $\mathbf{C} = \rho \mathbf{W}$, where $\mathbf{W}$ is a spatial weights matrix, and

$$\boldsymbol{\Sigma} = \begin{cases} \sigma^2 (\mathbf{I}_n - \rho \mathbf{W})^{-1} & \text{if } \mathbf{W} \text{ is symmetric} \\ \sigma^2 (\mathbf{D} - \rho \mathbf{W})^{-1} & \text{if a symmetric } \mathbf{W} \text{ is row-standardized} \end{cases}$$

where $\mathbf{D} = \text{diagonal}(\mathbf{W}_{1+}, \mathbf{W}_{2+}, \dots, \mathbf{W}_{n+})$, in which $\mathbf{W}_{i+}$ is the sum of entries in the i th row of the $\mathbf{W}$ matrix for $i = 1, 2, \dots, n$.

Let $\mathbf{D}^\dagger$ be defined as

$$\mathbf{D}^\dagger = \begin{cases} \mathbf{I}_n & \text{if a symmetric } \mathbf{W} \text{ is used} \\ \mathbf{D} & \text{if the row-standardized version of a symmetric } \mathbf{W} \text{ is used} \end{cases}$$

The gradients for the CAR model can be derived as

$$\frac{\partial \mathcal{L}}{\partial \boldsymbol{\beta}} = \frac{\mathbf{X}' \mathbf{D}^\dagger (\mathbf{I} - \rho \mathbf{W}) (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \rho} = -\frac{1}{2} \text{tr}(\mathbf{A}^{-1} \mathbf{W}) + \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})' \mathbf{D}^\dagger \mathbf{W} (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2\sigma^2}$$

$$\frac{\partial \mathcal{L}}{\partial \sigma^2} = -\frac{n}{2\sigma^2} + \frac{(\mathbf{y} - \mathbf{X}\boldsymbol{\beta})' \mathbf{D}^\dagger (\mathbf{I}_n - \rho \mathbf{W}) (\mathbf{y} - \mathbf{X}\boldsymbol{\beta})}{2(\sigma^2)^2}$$

where $\mathbf{A} = \mathbf{I}_n - \rho \mathbf{W}$.

Specifying the Spatial Weights Matrix

The spatial weights matrix $\mathbf{W}$ plays a vital role in spatial econometric modeling. If you fit a purely linear model without SLX effects, you do not need a $\mathbf{W}$ matrix. For other types of models in PROC CSPATIALREG, you need to provide a spatial weights matrix to fit the model. Although how you create the $\mathbf{W}$ matrix is often problem-specific, there are some general guidelines to consider. Two common ways to create the $\mathbf{W}$ matrix are k -order binary contiguity matrices and k -nearest-neighbor matrices (Elhorst 2013).

k -Order Binary Contiguity Matrices

To create the $\mathbf{W}$ matrix by using k -order binary contiguity matrices, you start with the spatial contiguity matrix $\mathbf{C}$. In the case of the first-order neighbors ($k = 1$), a value of 1 for the (i, j) th entry in $\mathbf{C}$ indicates that the two units i and j are neighbors to each other, and 0 indicates otherwise. The neighbor relationship is often defined based on sharing of a common boundary. To generalize this, a k -order neighbor ($k \geq 2$) of a unit i can be any units whose neighbors are $(k - 1)$ -order neighbors of unit i . In this sense, the two units i and j that are not first-order neighbors can still be second-order neighbors if unit j is the neighbor to a first-order neighbor of unit i .

As an example, a first-order binary contiguity matrix might look like the following:

$$\mathbf{C} = \begin{pmatrix} \text{SID} & \text{L1} & \text{L2} & \text{L3} & \text{L4} \\ \text{L1} & 0 & 1 & 0 & 1 \\ \text{L2} & 1 & 0 & 0 & 0 \\ \text{L3} & 0 & 0 & 0 & 1 \\ \text{L4} & 1 & 0 & 1 & 0 \end{pmatrix}$$

The diagonal elements of $\mathbf{C}$ are zeros because, in general, a unit is not considered to be a neighbor of itself. Moreover, the two units L2 and L4 are neighbors of L1; L2 has L1 as its only neighbor; L3 has L4 as its only neighbor; and L4 has L1 and L3 as its neighbors. You can create the spatial weights matrix $\mathbf{W}$ by row-standardizing the contiguity matrix $\mathbf{C}$. To do so, you divide entries in each row of $\mathbf{C}$ by the sum of that row. The spatial weights matrix $\mathbf{W}$, which is the row-standardized version of $\mathbf{C}$, is as follows:

$$\mathbf{W} = \begin{pmatrix} \text{SID} & \text{L1} & \text{L2} & \text{L3} & \text{L4} \\ \text{L1} & 0 & \frac{1}{2} & 0 & \frac{1}{2} \\ \text{L2} & 1 & 0 & 0 & 0 \\ \text{L3} & 0 & 0 & 0 & 1 \\ \text{L4} & \frac{1}{2} & 0 & \frac{1}{2} & 0 \end{pmatrix}$$

k -Nearest-Neighbor Matrices

To create the $\mathbf{W}$ matrix by using k -nearest-neighbor matrices, you can start by creating a spatial contiguity matrix based on a distance metric. Let d_{ij} denote the distance between the two units i and j , which might be the Euclidean distance between centroids of the two spatial units. Let $(\text{lon}_i, \text{lat}_i)$ and $(\text{lon}_j, \text{lat}_j)$ be the centroids of units i and j , where $1 \leq i, j \leq n$, and lon and lat denote the longitude and latitude, respectively. Under the Euclidean distance metric, the distance d_{ij} between units i and j is

$$d_{ij} = \sqrt{(\text{lat}_i - \text{lat}_j)^2 + (\text{lon}_i - \text{lon}_j)^2}$$

After computing the distance between the unit i and other units under a certain metric, you sort d_{ij} in ascending order; for example, $d_{ij_1} \leq d_{ij_2} \leq \dots \leq d_{ij_k} \leq \dots \leq d_{ij_{n-1}}$. For a given k , let $N_k(i) = \{j_1, j_2, \dots, j_k\}$ be the set that contains the indices of k -nearest neighbors of unit i ; then the (i, j) th entries of the contiguity matrix $\mathbf{C}$ are defined as

$$C_{ij} = \begin{cases} 1 & \text{if } j \in N_k(i) \\ 0 & \text{otherwise} \end{cases}$$

The (i, j) th entry of the corresponding row-standardized matrix $\mathbf{W}$ is $W_{ij} = C_{ij} \left\{ \sum_{j \in N_k(i)} C_{ij} \right\}^{-1}$.

Unlike the k -order binary contiguity matrix, which is often symmetric by construction, k -nearest-neighbor matrices can be asymmetric. To obtain symmetric k -nearest neighbor matrices, you can define the (i, j) th entries of the contiguity matrix $\mathbf{C}$ as follows:

$$C_{ij} = \begin{cases} 1 & \text{if } j \in N_k(i) \text{ or } i \in N_k(j) \\ 0 & \text{otherwise} \end{cases}$$

In addition to the Euclidean distance measure, you can use other distance metrics as appropriate. A variant of k -nearest-neighbor matrices $\mathbf{C}^*$ that is used in some empirical studies defines its (i, j) th entries as

$$C_{ij}^* = \begin{cases} 1 & \text{if } d_{ij} \leq d_{\text{cutoff}} \\ 0 & \text{otherwise} \end{cases}$$

where d_{cutoff} is a prespecified threshold distance.

In addition to the two constructions of spatial weights matrices that are presented earlier, see Elhorst (2013) and the references therein for more information about other ways to create a spatial weights matrix. In practice, you can define the neighbor relation that is problem-specific. For example, you can define two spatial units that are far apart to be neighbors because they share some attributes (such as population sizes larger than 500,000).

The data table that you specify in the `WMAT=` option is row-standardized by default to create a spatial weights matrix. This means that if you specify `WMAT=C`, PROC CSPATIALREG row-standardizes the spatial contiguity matrix to create a spatial weights matrix. If you want to suppress row standardization, you must specify the `NONNORMALIZE` option in the PROC CSPATIALREG statement.

Compact Representation of the Spatial Weights Matrix

When the number of spatial units n increases, the amount of memory that it takes to store n^2 entries of the spatial contiguity matrix $\mathbf{C}$ or the spatial weights matrix $\mathbf{W}$ increases dramatically. To circumvent the storage issue, PROC CSPATIALREG enables you to provide a compact representation of $\mathbf{W}$ (or $\mathbf{C}$) when appropriate. For the compact matrix representation, you provide a data table that contains three variables by using the `WMAT=` option. The first two variables identify the row r and column c of $\mathbf{W}$ (or $\mathbf{C}$), and (r, c) can be expressed either as numerical indices or as values of the variable that you specify in the `SPATIALID` statement. The third variable contains the nonzero value of $\mathbf{W}$ (or $\mathbf{C}$) for row r and column c . In this compact representation, the number of observations in the data table that you specify in the `WMAT=` option equals the total number of nonzero entries in $\mathbf{W}$ (or $\mathbf{C}$).

You must use a `SPATIALID` statement if you want to use the compact representation of the spatial contiguity or spatial weights matrix. In the compact representation, the first two variables of the data table that you specify in the `WMAT=` option must be of the same type. First, the first two columns in that data table can

be the row and column index for each nonzero entry in **W** (or **C**). In this case, the SPATIALID variable is numeric type. Alternatively, the first two columns in the WMAT= data table can be characters that are the names of two neighboring spatial units in **W** (or **C**). In this second case, the SPATIALID variable is character type.

For example, the compact representation of the spatial weights matrix **W**,

$$\mathbf{W} = \begin{pmatrix} 0 & 0.5 & 0 & 0.5 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 0.5 & 0 & 0.5 & 0 \end{pmatrix}$$

would look like the following:

```
data Ws;
  input SID cSID Weight;
  datalines;
  1 2 0.5
  1 4 0.5
  2 1 1.0
  3 4 1.0
  4 1 0.5
  4 3 0.5
  ;
run;
```

For the spatial contiguity matrix **C**,

$$\mathbf{C} = \begin{pmatrix} 0 & 1 & 0 & 1 \\ 1 & 0 & 0 & 0 \\ 0 & 0 & 0 & 1 \\ 1 & 0 & 1 & 0 \end{pmatrix}$$

the compact representation would look like the following:

```
data Cs;
  input SID cSID Weight;
  datalines;
  1 2 1.0
  1 4 1.0
  2 1 1.0
  3 4 1.0
  4 1 1.0
  4 3 1.0
  ;
run;
```

If the spatial weights matrix is the same as matrix **W** in the section “*k*-Order Binary Contiguity Matrices” on page 671, its compact representation would be as follows:

```
data Ws2;
  input SID $ cSID $ Weight;
  datalines;
  L1 L2 0.5
```

```

L1 L4 0.5
L2 L1 1.0
L3 L4 1.0
L4 L1 0.5
L4 L3 0.5
;
run;

```

If the spatial contiguity matrix is the same as matrix **C** in the section “*k*-Order Binary Contiguity Matrices” on page 671, its compact representation can be given in the data set **Cs2** as follows:

```

data Cs2;
  input SID $ cSID $ Weight;
  datalines;
L1 L2 1.0
L1 L4 1.0
L2 L1 1.0
L3 L4 1.0
L4 L1 1.0
L4 L3 1.0
;
run;

```

Spatial ID Matching

Depending on the type of model that you use in PROC CSPATIALREG, you might need to specify two data tables: one in the **DATA=** option and the other in the **WMAT=** option. In such cases, you must use a **SPATIALID** statement to specify a spatial ID variable in order to match observations in these two data tables.

As an example, assume that the data table that you specify in the **DATA=** option looks like the following:

```

data mylib.Example;
  input SID $ x1 x2 y;
  datalines;
L1 0.3 0.5 0.9
L3 -0.7 0.8 -0.4
L2 0.4 -1.2 0.6
L8 -1.7 1.2 -0.5
L4 1.4 0.9 0.3
L5 2.3 1.5 1.9
L7 -0.9 -0.8 -1.3
L6 1.4 -1.6 -2.0
;
run;

```

Suppose that the spatial contiguity matrix that you specify in the **WMAT=** option looks like the following:

```

data mylib.Cmat;
  input SID $ L1 L8 L3 L4 L7 L6 L5 L2;
  datalines;
L1 0 1 0 1 0 1 0 1
L2 1 0 0 0 1 0 0 0
L6 1 0 1 0 0 0 0 0

```

```

L4  1 0 0 0 1 0 0 0
L3  0 0 0 0 1 1 0 0
L7  0 0 1 1 0 0 0 1
L5  0 1 0 0 0 0 0 0
L8  1 0 0 0 0 0 1 0
;
run;

```

As you can see, rows in the two data tables `mylib.Example` and `mylib.Cmat` do not share identically sorted SID values. The second row in the `Example` data table contains the observation for a spatial unit L3, and its neighbor information is given in the fifth row of the `mylib.Cmat` data table. Moreover, the rows and columns of the spatial weights data table `mylib.Cmat` are not in the same order. The following SAS statements fit a SAR model to these data:

```

proc cspatialreg data=mylib.Example Wmat=mylib.Cmat;
  model y=x1 x2/type=SAR;
  spatialid SID;
run;

```

The `SPATIALID` statement enables you to match rows and columns of the `mylib.Cmat` data table in addition to rows of the `mylib.Example` and `mylib.Cmat` data tables.

Parameter Space of Spatial Coefficients

All models except linear regression models require that the parameters ρ and/or λ satisfy some assumptions to ensure consistency of the maximum likelihood estimator (Elhorst 2013). For SDMs and SAR models, the Jacobian term involves the log-determinant of $\mathbf{I} - \rho \mathbf{W}_1$, and the parameter space of ρ is specified such that $\mathbf{I} - \rho \mathbf{W}_1$ is nonsingular. For the SEM, SDEM, SMA, and SDMA models, the Jacobian term involves the log-determinant of $\mathbf{I} - \lambda \mathbf{W}_1$, and the parameter space of λ is specified such that $\mathbf{I} - \lambda \mathbf{W}_1$ is nonsingular. For the SAC, SDAC, SARMA, and SDARMA models, both $\mathbf{I} - \rho \mathbf{W}_1$ and $\mathbf{I} - \lambda \mathbf{W}_2$ must be nonsingular. As a result, the parameter space of ρ and λ is often specified such that both $\mathbf{I} - \rho \mathbf{W}_1$ and/or $\mathbf{I} - \lambda \mathbf{W}_1$ are nonsingular.

In the `CSPATIALREG` procedure, the parameter space of the spatial coefficients ρ and λ depends on the spatial weights matrix $\mathbf{W}$ that you choose. For a given $\mathbf{W}$, the parameter space of the parameters ρ and λ in `PROC CSPATIALREG` is determined as follows:

1. For a symmetric $\mathbf{W}$, the nonsingularity condition requires $\rho \in (\omega_{\min}^{-1}, \omega_{\max}^{-1})$ and $\lambda \in (\omega_{\min}^{-1}, \omega_{\max}^{-1})$. Here $\omega_{\min}$ and $\omega_{\max}$ denote the smallest (that is, most negative) and largest real eigenvalues of $\mathbf{W}$, respectively.
2. If $\mathbf{W}$ is symmetric and subsequently row-standardized, the nonsingularity condition requires $\rho \in (\omega_{\min}^{*-1}, 1)$ and $\lambda \in (\omega_{\min}^{*-1}, 1)$. Here $\omega_{\min}^*$ denotes the smallest purely real eigenvalue of the row-standardized $\mathbf{W}$.
3. If $\mathbf{W}$ is asymmetric and subsequently row-standardized, the nonsingularity condition requires $\rho \in (r_{\min}^{*-1}, 1)$ and $\lambda \in (r_{\min}^{*-1}, 1)$. Here $r_{\min}^*$ denotes the smallest purely real eigenvalue of the row-standardized $\mathbf{W}$.

4. When Taylor or Chebyshev approximation is used for SDMs and SAR models, $\mathbf{W}$ is required to be row-standardized. In these cases, the restriction on the spatial autoregressive coefficient ρ is $\rho \in (-1, 1)$.
5. When Taylor or Chebyshev approximation is used for SEMs and SDEMs, $\mathbf{W}$ is required to be row-standardized. In these cases, the restriction on the spatial autocorrelation coefficient λ is $\lambda \in (-1, 1)$.

For CAR models, only symmetric spatial weights matrices are allowed. As a result, the parameter space of ρ is $\rho \in (\omega_{\min}^{-1}, \omega_{\max}^{-1})$.

For the interpretation of the spatial coefficient ρ , a significant and positive (or negative) value of ρ in the CAR, SAR, SDM, SAC, SDAC, SARMA, and SDARMA models would suggest positive (or negative) spatial lag dependence. Similarly, a significant and positive (or negative) value of λ in the SEM, SDEM, SAC, and SDAC models would suggest positive (or negative) spatial error dependence, which is contrary to the SMA, SDMA, SARMA, and SDARMA models. For the SMA, SDMA, SARMA, and SDARMA models, a significant and positive (or negative) value of λ would suggest negative (or positive) spatial error dependence.

Approximations to the Jacobian

To obtain maximum likelihood estimates for all models except linear regression models, the Jacobian term must be computed, because it appears in the log-likelihood function. The Jacobian term is $\ln |\mathbf{I}_n - \rho \mathbf{W}|$ for SDMs and SAR models and $\ln |\mathbf{I}_n - \lambda \mathbf{W}|$ for SEMs and SDEMs, where n is the number of observations and $\mathbf{W}$ is the spatial weights matrix. When n is not large, the Jacobian is computed as follows,

$$\ln |\mathbf{I}_n - \rho \mathbf{W}| = \sum_{i=1}^n \ln |1 - \rho \omega_i|$$

where ω_i are the eigenvalues of $\mathbf{W}$ for $i = 1, 2, \dots, n$. Such a method requires you to precompute all eigenvalues of $\mathbf{W}$. This works fine for small data sets, but when n is large, computing the Jacobian term by using the eigenvalue method can be computationally infeasible. Instead, you can use approximations to the Jacobian.

The CSPATIALREG procedure supports two different approximations to the Jacobian. For SDMs, SEMs, SDEMs, and SAR models, you can approximate the Jacobian by using either Taylor or Chebyshev approximation. Using SDMs and SAR models as an example, the two approximations for the Jacobian term can be described as follows (for more information, see LeSage and Pace 2009, and the references therein):

- Taylor approximation uses finite, lower-order series to approximate the log-determinant as

$$\ln |\mathbf{I}_n - \rho \mathbf{W}| \approx - \sum_{k=1}^q \frac{\rho^k \text{tr}(\mathbf{W}^k)}{k}$$

- Chebyshev approximation uses finite, lower-order Chebyshev polynomials of the first kind to approximate the log-determinant as

$$\ln |\mathbf{I}_n - \rho \mathbf{W}| \approx \sum_{k=0}^q c_k(\rho) \text{tr}(T_k(\mathbf{W}))$$

where $T_0(\mathbf{W}) = \mathbf{I}_n$, $T_1(\mathbf{W}) = \mathbf{W}$, and $T_{k+1}(\mathbf{W}) = 2\mathbf{W}T_k(\mathbf{W}) - T_{k-1}(\mathbf{W})$ for $k = 1, 2, \dots, q$. The coefficients $c_k(\rho)$ are defined as

$$c_k(\rho) = \begin{cases} \frac{1}{q+1} \sum_{j=0}^q \ln(1 - \rho \cos \theta_j) \cos(k\theta_j) & \text{if } k = 0 \\ \frac{2}{q+1} \sum_{j=0}^q \ln(1 - \rho \cos \theta_j) \cos(k\theta_j) & \text{if } k > 0 \end{cases}$$

with $\theta_j = (j+1)\pi/(q+1)$ for $j = 0, 1, \dots, q$.

The traces of powers of $\mathbf{W}$ can be computed exactly or approximated using Monte Carlo simulation. The Monte Carlo simulation is done as follows,

$$\text{tr}(\mathbf{W}^k) \approx \frac{1}{M} \sum_{l=1}^M \frac{n}{\mathbf{u}_l' \mathbf{u}_l} \mathbf{u}_l' \mathbf{W}^k \mathbf{u}_l$$

where $\mathbf{u}_l \stackrel{\text{iid}}{\sim} N(\mathbf{0}, \mathbf{I}_n)$ and M is the total number of Monte Carlo samples.

When you apply these two approximations, it is often assumed that the maximum eigenvalue of $\mathbf{W}$ equals 1 and the minimum eigenvalue of $\mathbf{W}$ is greater than or equal to -1 (see LeSage and Pace 2009, and the references therein). One way to satisfy this assumption is to use a row-standardized spatial weights matrix that is similar to a symmetric matrix. If the spatial weights matrix is not symmetric or similar to a symmetric matrix, it becomes more difficult to apply Chebyshev approximation and thus requires extra care (LeSage and Pace 2009).

When you request an approximation to the Jacobian, the choices that you need to make might include the approximation method to use (that is, Taylor or Chebyshev approximation), the order of series q , and the number of Monte Carlo samples (that is, M). Your choice can be accommodated through the **APPROXIMATION=** option in the PROC CSPATIALREG statement. For the approximation method, you can use the keyword TAYLOR in the APPROXIMATION= option to request Taylor approximation. Otherwise, the approximation method defaults to Chebyshev approximation. You specify ORDER= q in the APPROXIMATION= option to request a series of order q when approximating the log-determinant. In addition, you specify NMC= M in the APPROXIMATION= option to request M Monte Carlo samples to be drawn when approximating the traces of powers of $\mathbf{W}$. In addition, you can use the SEED= suboption of the APPROXIMATION= option to specify an integer seed for a random number generator to replicate your analysis.

Impact Estimation

For models in PROC CSPATIALREG that include endogenous interactions or exogenous interactions, the interpretation of marginal effects is not as straightforward as it is in the classical linear regression model. For example, consider the following SDM model:

$$\mathbf{y} = \rho \mathbf{W} \mathbf{y} + \mathbf{X} \boldsymbol{\beta} + \mathbf{W} \mathbf{X} \boldsymbol{\theta} + \boldsymbol{\epsilon}$$

where $\boldsymbol{\epsilon} \sim N(\mathbf{0}, \sigma^2 \mathbf{I})$.

For an explanatory variable x_p in the model,

$$\frac{\partial y_i}{\partial x_{jp}} = [\mathbf{A}^{-1}(\beta_p \mathbf{I}_n + \theta_p \mathbf{W})]_{ij}$$

where $\mathbf{A} = \mathbf{I} - \rho\mathbf{W}$ and $[\mathbf{B}]_{ij}$ denotes the (i, j) th element of the matrix $\mathbf{B}$ for $i, j = 1, 2, \dots, n$.

According to $\frac{\partial y_i}{\partial x_{jp}}$, you can see that the impact of changes in x_p at a location j on the dependent variable differ from one location to another. To quantify the marginal effects of an explanatory variable x_p in the model, LeSage and Pace (2009) propose the average direct impacts ($\bar{M}(p)_{\text{direct}}$), the average total impacts ($\bar{M}(p)_{\text{total}}$), and the average indirect impacts ($\bar{M}(p)_{\text{indirect}}$) as follows:

$$\begin{aligned}\bar{M}(p)_{\text{direct}} &= \frac{1}{n} \sum_{i=1}^n [\mathbf{A}^{-1}(\beta_p \mathbf{I}_n + \theta_p \mathbf{W})]_{ii} \\ \bar{M}(p)_{\text{total}} &= \frac{1}{n} \sum_{i=1}^n \sum_{j=1}^n [\mathbf{A}^{-1}(\beta_p \mathbf{I}_n + \theta_p \mathbf{W})]_{ij} \\ \bar{M}(p)_{\text{indirect}} &= \bar{M}(p)_{\text{total}} - \bar{M}(p)_{\text{direct}}\end{aligned}$$

In addition, LeSage and Pace (2009) describe how to use Monte Carlo simulation to quantify uncertainty that is associated with the three impact estimates. First, the empirical distribution for parameters (the regression coefficients and, if applicable, the spatial dependence parameter ρ) is assumed to be a multivariate normal distribution where the mean vector contains the point estimates and the covariance matrix is estimated based on the maximum likelihood estimation. Second, M samples are drawn from the empirical distribution and for each sample being drawn, $\bar{M}(p)_{\text{direct}}$, $\bar{M}(p)_{\text{total}}$, and $\bar{M}(p)_{\text{indirect}}$ are computed. Based on these random samples, the sample mean and standard deviation for each of three impact estimates can be computed.

When $\bar{M}(p)_{\text{direct}}$, $\bar{M}(p)_{\text{total}}$, and $\bar{M}(p)_{\text{indirect}}$ are computed, the inverse of $\mathbf{A} = \mathbf{I}_n - \rho\mathbf{W}$ needs to be computed for each random sample drawn. Since the exact inversion of $\mathbf{A}$ can be computationally intensive, approximation can be helpful when it is applicable. When the spectral radius of $\rho\mathbf{W}$ is less than 1, $\mathbf{A}^{-1}$ can be approximated by the partial sums of Neumann series as

$$(\mathbf{I}_n - \rho\mathbf{W})^{-1} = \sum_{o=0}^{+\infty} (\rho\mathbf{W})^o \approx \mathbf{I}_n + \rho\mathbf{W} + \dots + \rho^o \mathbf{W}^o$$

The IMPACT option in the PROC CSPATIALREG statement computes $\bar{M}(p)_{\text{direct}}$, $\bar{M}(p)_{\text{total}}$, and $\bar{M}(p)_{\text{indirect}}$ by using the Monte Carlo simulation that is proposed by LeSage and Pace (2009). In particular, you specify NMC= M in the IMPACT option to request that M samples be drawn from the empirical distribution of the relevant model parameters. You use the ORDER= O suboption of the IMPACT option to specify the highest order of Neumann series to approximate $\mathbf{A}^{-1}$. You use the SEED= suboption of the IMPACT option to specify an integer seed for a random number generator to replicate your results.

Impact estimation is not supported for models that include any of the following: a classification variable, interactions between regressions, a BOUNDS statement, or a RESTRICT statement. In addition, Monte Carlo simulation is not needed to compute summary statistics for $\bar{M}(p)_{\text{direct}}$, $\bar{M}(p)_{\text{total}}$, and $\bar{M}(p)_{\text{indirect}}$ for linear, SLX, SEM, SDEM, SMA, and SDMA models because a closed-form solution is available ($\bar{M}(p)_{\text{direct}} = \beta_p$, $\bar{M}(p)_{\text{total}} = \beta_p + \theta_p$, and $\bar{M}(p)_{\text{indirect}} = \theta_p$). In these models, any NMC=, ORDER=, and SEED= suboptions that you specify in the IMPACT option are ignored. When you specify the IMPACT option for SAR, SDM, SAC, SDAC, SARMA, and SDARMA models, the spatial weights matrix $\mathbf{W}$ must be row-standardized. Moreover, the restriction $-1 < \rho < 1$ is imposed for SAR and SDM models and the restrictions $-1 < \rho < 1$ and $-1 < \lambda < 1$ are imposed for SAC, SDAC, SARMA, and SDARMA models. With the restriction $-1 < \rho < 1$, the average total impacts $\bar{M}(p)_{\text{total}}$ can be simplified as

$$\bar{M}(p)_{\text{total}} = \frac{1}{1 - \rho}(\beta_p + \theta_p)$$

Multiple Model Comparison

This section describes how you can fit multiple models, compare their corresponding fit statistic, and identify the model that provides the best fit to the data according to some criteria, such as AIC and SBC.

To fit multiple models, you can specify the `TYPE=ALL` or `TYPE=AUTO` option in the `MODEL` statement or `PROC CSPATIALREG` statement. The `TYPE=AUTO` option enables you to fit a selected subset of models among all models that `PROC CSPATIALREG` supports.

- If you specify the `TYPE=AUTO` option without the `SPATIALEFFECTS` statement, each of the seven available models—`CAR`, `LINEAR`, `SAC`, `SAR`, `SARMA`, `SEM`, and `SMA`—is fit using the regressors that you specify in the `MODEL` statement.
- If you specify both the `TYPE=AUTO` option and `SPATIALEFFECTS` statement, each of the available seven models—`CAR2`, `SDAC`, `SDARMA`, `SDM`, `SDMA`, and `SLX`—is fit using both the regressors that you specify in the `MODEL` statement and the spatial lagged regressors that you specify in the `SPATIALEFFECTS` statement, respectively.

The `TYPE=ALL` option enables you to fit all fourteen models that `PROC CSPATIALREG` supports.

- If you specify the `TYPE=ALL` option without the `SPATIALEFFECTS` statement, `PROC CSPATIALREG` fits seven models. In this case, each of the seven models—`CAR`, `LINEAR`, `SAC`, `SAR`, `SARMA`, `SEM`, and `SMA`—is fit using the regressors that you specify in the `MODEL` statement. This is equivalent to specifying the `TYPE=AUTO` option without the `SPATIALEFFECTS` statement.
- If you specify both the `TYPE=ALL` option and the `SPATIALEFFECTS` statement, `PROC CSPATIALREG` fits all fourteen models. On the one hand, each of the seven models—`CAR`, `LINEAR`, `SAC`, `SAR`, `SARMA`, `SEM`, and `SMA`—is fit using only the regressors that you specify in the `MODEL` statement. On the other hand, another seven models—`CAR2`, `SDAC`, `SDARMA`, `SDM`, `SDMA`, and `SLX`—are fit using both the regressors and the spatial lagged regressors that you specify in the `MODEL` statement and `SPATIALEFFECTS` statement, respectively.

When you fit multiple models by specifying the `TYPE=ALL` or `TYPE=AUTO` option, the following syntax is not supported:

- `BOUNDS`, `INIT`, `RESTRICT`, and `TEST` statements
- `APPROXIMATION=` option in the `PROC CSPATIALREG` statement

Parameter Naming Conventions for RESTRICT, TEST, BOUNDS, and INIT Statements

This section describes how you can refer to the parameters in the MODEL and SPATIALEFFECTS statements when you use the RESTRICT, TEST, BOUNDS, or INIT statement. The following examples use the RESTRICT statement, but the same remarks apply to naming parameters when you use the TEST, BOUNDS, or INIT statement. The names of the parameters are displayed in the “Parameter Estimates” table if you specify the option. If a parameter name contains a blank or some other special character (such as ‘*’, ‘-’, ‘(’, or ‘)'), then you must use the internal name of the parameter to refer to that parameter in the RESTRICT, TEST, BOUNDS, or INIT statement. You can specify the PRINTINTERNALNAMES option in the PROC CSPATIALREG statement if you want to see the internal names of the parameters. When you specify the PRINTINTERNALNAMES option, the “Parameter Estimates” table includes an additional column that shows the internal name of each parameter.

To impose a restriction on a parameter that is related to a regressor in the MODEL statement, you simply use the name of the regressor itself. Suppose that your model is

```
model y = x1-x3 / type=SAR;
```

where x1–x3 are continuous variables. Suppose you want to restrict the parameter that is associated with the regressor x3 to be greater than 1.7. You should provide the following statement:

```
RESTRICT x3 > 1.7;
```

To impose a restriction on a parameter that is associated with a regressor in the SPATIALEFFECTS statement, you can form the name of the parameter by adding the prefix W_ to the name of the regressor. Suppose that your MODEL and SPATIALEFFECTS statements are as follows:

```
model y = x1-x3 / type=SAR;  
spatialeffects x1 x2 x3;
```

Suppose you want to restrict the parameter that is related to the x3 regressor in the SPATIALEFFECTS statement to be less than 1.0. You should refer to the parameter as W_x3 and provide the following statement:

```
RESTRICT W_x3 < 1.0;
```

Even though the regressor x3 appears in both the MODEL and SPATIALEFFECTS statements, the parameter that is associated with x3 in the MODEL statement is, of course, different from the parameter that is associated with x3 in the SPATIALEFFECTS statement. Thus, when you use the name of a regressor in a RESTRICT statement without any prefix, it refers to the parameter that is associated with that regressor in the MODEL statement. Meanwhile, when you use the name of a regressor in a RESTRICT statement with the prefix W_, it refers to the parameter that is associated with that regressor in the SPATIALEFFECTS statement. Note that the intercept is not included in the SPATIALEFFECTS statement.

Referring to Class Level Parameters

When your MODEL includes a classification variable, you can impose restrictions on the parameters associated with each of the levels that are related to the classification variable as follows.

Suppose that your classification variable is named *C* and has three levels: 0, 1, and 2. Suppose that your model is the following:

```
class C;
model y = x1 x2 C;
```

Adding a classification variable as a regressor to your model introduces additional parameters to your model, each of which is associated with one of the levels of the classification variable. You can form the name of the parameter that is associated with a particular level of your classification variable by inserting the underscore character between the name of the classification variable and the value of the level. Thus, to restrict the parameter that is associated with level 0 of the classification variable *C* to always be greater than 0.7, you refer to the parameter as *C_0* and provide the following statement:

```
RESTRICT C_0 > 0.7;
```

Referring to Parameters Associated with Interactions between Regressors

When a regressor in your model involves an interaction between other regressors, you can impose restrictions on the parameters that are associated with the interaction as described in this section.

Suppose you have the following model:

```
model y = x1 x2 x3*x4;
```

You can form the name of the parameter that is associated with the interaction regressor *x3*x4* by replacing the multiplication sign with an underscore. Thus, *x3_x4* refers to the parameter that is associated with the interaction regressor *x3*x4*.

You refer to interactions between regressors and CLASS variables in exactly the same way. Suppose you have a CLASS variable named *C* that has three levels (0, 1, and 2), and your model is the following:

```
class C;
model y = x1 x2 C*x3;
```

The interaction between the continuous variable *x3* and the CLASS variable *C* introduces three additional parameters, which are named *x3_C_0*, *x3_C_1*, and *x3_C_2*. Note that, although the order of the terms in the interaction is *C* followed by *x3*, the name of the parameter that is associated with the interaction is formed by placing the name of the continuous variable *x3* first, followed by an underscore, followed by the name of the CLASS variable *C*, then another underscore, and then the level value. Once again, depending on the parameterization that you specify in your CLASS statement, for each interaction in your model that involves a CLASS variable, one of the parameters that are associated with that interaction can be dropped from your model before optimization.

The name of a parameter that is associated with a nested interaction is formed in a slightly different way. Suppose you have a CLASS variable named *C* that has three levels (0, 1, and 2) and your model is the following:

```
class C;
model y = x1 x2 x3 (C);
```

The nested interaction between the continuous variable `x3` and the CLASS variable `C` introduces three additional parameters, which are named `x3_C__0`, `x3_C__1`, and `x3_C__2`. Note how the name in each case was formed from the name of the regressor by replacing the left and right parentheses with underscores and then appending another underscore, followed by the level value.

Referring to Class Level Parameters with Negative Values

When the value of a level is a negative number, you must replace the minus sign with an underscore when you form the name of the parameter that is associated with that particular level of the classification variable. For example, suppose your classification variable is named `D` and has four levels: `-1`, `0`, `1`, and `2`. Suppose that your model is the following:

```
class D;
model y = x1 x2 D;
```

To restrict the parameter that is associated with level `-1` of the classification variable `D` to always be less than `0.4`, you refer to the parameter as `D__1` (note that there are two underscores in this parameter name: one to connect the name of the classification variable to its value and the other to replace the minus sign in the value itself) and provide the following statement:

```
RESTRICT D__1 < 0.4;
```

Dropping a Class Level Parameter to Avoid Collinearity

Depending on the parameterization that you impose on your classification variable, one of the parameters that are associated with its levels might be dropped from your model before optimization in order to avoid collinearity. For example, when the default parameterization GLM is imposed, the parameter that is associated with the last level of your classification variable is dropped before optimization. If you attempt to impose a restriction on a dropped parameter by using the `RESTRICT` statement, PROC CSPATIALREG issues an error message in the log.

For example, suppose again that your classification variable is named `C` and has three levels: `0`, `1`, and `2`. Suppose that your model is the following:

```
class C;
model y = x1 x2 C;
```

Because no additional options are specified in the CLASS statement, GLM parameterization is assumed. This means that the parameter named `C_2` (which is the parameter associated with the last level of your classification variable) is dropped from your model before the optimizer is invoked. Therefore, you get an error if you attempt to restrict the `C_2` parameter in any way by referring to it in a `RESTRICT` statement. For example, the following `RESTRICT` statement will generate an error:

```
RESTRICT C_2 < 0.3;
```

Referring to Implicit Parameters

For all models in PROC CSPATIALREG, one or more implicit parameters are added to your model before optimization. You can impose restrictions on these implicit parameters as follows.

If you have a linear model or an SLX model, the `_sigma2` parameter is added to your model. For the SDM or SAR model, the `_rho` and `_sigma2` parameters are added to your model. For the SEM or SDEM, the `_lambda` and `_sigma2` parameters are added to your model.

Whenever your model type dictates the addition of one or more of these implicit parameters, you can impose restrictions on the implicit parameters by referring to them by name. For example, assuming that your model type implies the existence of the `_rho` parameter, you can restrict `_rho` to be greater than 0 as follows:

```
RESTRICT _rho > 0.0;
```

Computational Resources

The time and memory that PROC CSPATIALREG requires are proportional to the number of parameters in the model and the number of observations in the data that you are analyzing. Less time and memory are required for smaller models and fewer observations. When you run PROC CSPATIALREG in the high-performance distributed environment, the amount of time that is required is also affected by the number of nodes and the number of threads per node when the optimization task is distributed.

The method that you use to calculate the variance-covariance matrix and the optimization method also affect the time and memory resources. All optimization methods available through the `METHOD=` option have similar memory use requirements. The processing time might differ among methods, depending on the number of iterations and functional calls that are needed. The data is read into memory to save processing time. If not enough memory is available to hold the data, the CSPATIALREG procedure stores the data in a utility file on disk and rereads the data as needed from this file, substantially increasing the execution time of the procedure. The gradient and the variance-covariance matrix must be held in memory. If the model has p parameters, including the intercept, then you need at least $8 * (p + p * (p + 1)/2)$ bytes of memory. The processing time is also a function of the number of iterations that are needed to converge to a solution for the model parameters. The number of iterations that are needed cannot be known in advance. You can use the `MAXITER=` option to limit the number of iterations that PROC CSPATIALREG performs. You can alter the convergence criteria by using the nonlinear optimization options available in the PROC CSPATIALREG statement. For a list of all the nonlinear optimization options, see the section “[Optimization Control Options](#)” on page 649.

Covariance Matrix Types

The CSPATIALREG procedure enables you to specify the estimation method for the covariance matrix. You have three choices, which you can specify in either the PROC CSPATIALREG or MODEL statement: the COVEST=HESSIAN option estimates the covariance matrix based on the inverse of the Hessian matrix, the COVEST=OP option uses the outer product of gradients, and the COVEST=QML option produces the covariance matrix based on both the Hessian and outer product matrices. By default, COVEST=HESSIAN.

Although all three methods produce asymptotically equivalent results, they differ in computational intensity and produce results that might differ in finite samples. The COVEST=OP option provides the covariance matrix that is usually the easiest to compute. In some cases, the OP approximation is considered more efficient than the Hessian or QML approximation because it contains fewer random elements. The QML approximation is computationally the most complex, because it requires both the outer product of gradients and the Hessian matrix. In most cases, the OP or Hessian approximation is preferred to the QML approximation. You need to use the QML approximation in some cases when the model is misspecified and the information matrix equality does not hold.

For SDMs, SEMs, SDEMs, and SAR models, only COVEST=HESSIAN is supported.

Displayed Output

PROC CSPATIALREG produces the following displayed output.

Class Level Information

If you specify the CLASS statement, the CSPATIALREG procedure displays a table that contains the following information:

- CLASS variable name
- number of levels of the CLASS variable
- list of values of the CLASS variable

Model Fit Summary

When you fit a single model in PROC CSPATIALREG, the “Model Fit Summary” table contains the following information:

- dependent variable name
- number of observations used
- data table name
- name of the spatial weights data table (specified by the WMAT= option)
- spatial ID variable

- type of model that was fit
- log-likelihood value at the solution
- maximum absolute gradient at the solution
- number of iterations
- AIC value at the solution (a smaller value indicates a better fit)
- SBC value at the solution (a smaller value indicates a better fit)

Below the “Model Fit Summary” table is a statement about whether the algorithm successfully converged.

If you fit multiple models by using the TYPE=ALL or TYPE=AUTO option, the “Model Fit Summary” table contains the following information:

- dependent variable name
- number of observations used
- data table name
- name of the spatial weights data table (specified by the WMAT= option)
- spatial ID variable
- type of model that was fit

Parameter Estimates

The “Parameter Estimates” table displays the estimates of the model parameters, which include both regression coefficients and other, model-specific parameters. For the CAR, SAR, and SDM models, the table also displays estimates of the spatial autoregressive coefficient ρ and the variance of the error terms σ^2 . For the SDEM, SDMA, SEM, and SMA models, it also displays estimates of the spatial autocorrelation coefficient λ and the variance of the error terms σ^2 . For the linear and SLX models, the table also displays estimates of the variance of the error terms σ^2 . For SAC, SARMA, SDARMA, and SDAC models, it also displays estimates of the spatial autoregression coefficient ρ , the spatial autocorrelation coefficient λ , and the variance parameter σ^2 .

The internal name of the spatial autoregressive coefficient ρ is “_rho”. The t statistic that “Parameter Estimates” table displays for “_rho” is a test of the spatial autoregressive coefficient. In addition, “_lambda” is the internal name of the spatial autocorrelation coefficient λ , and “_sigma2” is the internal name of the variance parameter σ^2 .

Covariance of Parameter Estimates

If you specify the COVB option in the MODEL or PROC CSPATIALREG statement, the CSPATIALREG procedure displays the estimated covariance matrix, defined as the inverse of the information matrix, that is evaluated at the final iteration.

Correlation of Parameter Estimates

If you specify the CORRB option in the MODEL or PROC CSPATIALREG statement, the CSPATIALREG procedure displays the estimated correlation matrix. It is based on the Hessian matrix that is used in the final iteration.

OUTPUT OUT= Data Table

The OUTPUT statement creates a new data table that contains various estimates that you specify. You can request that the output data table contain the estimates of $\mathbf{x}'_i\boldsymbol{\beta}$, the expected value of the response variable, and the residual.

Because of potential space limitations on the client workstation, the data table that the OUTPUT statement creates does not contain the variables in the input data table.

ODS Table Names

PROC CSPATIALREG assigns a name to each table that it creates. You can use these names to denote the table when using the Output Delivery System (ODS) to select tables and create output data tables. These names are listed in [Table 13.3](#).

Table 13.3 ODS Tables Produced by PROC CSPATIALREG

Table Name	Description	Statement	Option
ClassInfo	Level information from the CLASS statement	CLASS	Default
ConvergenceStatus	Convergence status	MODEL	Default
CorrB	Correlation of parameter estimates	MODEL	CORRB
CovB	Covariance of parameter estimates	MODEL	COVB
FitModelSummary	Summary of nonlinear estimation	MODEL	Default
ImpactEstimates	Summary of direct, indirect, and total impact estimates	PROC CSPATIALREG	IMPACT
InitialParameterEstimates	Initial parameter estimates	PROC CSPATIALREG or MODEL	PRINTALL
IterationHistory	Optimization iteration history	PROC CSPATIALREG or MODEL	PRINTALL
ModelComparison	Model comparison for multiple models	PROC CSPATIALREG or MODEL	TYPE=AUTO or TYPE=ALL
OptimizationResults	Optimization results	PROC CSPATIALREG or MODEL	PRINTALL

Table 13.3 *continued*

Table Name	Description	Statement	Option
ParameterEstimates	Parameter estimates	MODEL	Default
TestResults	Hypothesis test statistics	TEST	Default
TimingDetails	Detailed summary of time used for all phases of execution	PROC CSPATIALREG	PRINTTIMING=(DETAILS)
TimingSummary	Summary of time used for main phases of execution	PROC CSPATIALREG	PRINTTIMING
ZNLOSettings	Nonlinear optimizer settings	PROC CSPATIALREG or MODEL	PRINTALL

Examples: CSPATIALREG Procedure

Example 13.1: Columbus Crime Data

Data Description and Objective

The data set `CrimeOH` contains data from Columbus, Ohio, about numbers of crimes (including residential burglaries and vehicle thefts) and possible determinants of these crimes. This data set comes from Anselin (1988).

The variable `Crime` represents the number of crimes in 49 Columbus neighborhoods. Additional variables in the data set that you want to evaluate as determinants of these crimes include `Income` (household income by \$1,000) and `HValue` (housing value by \$1,000). Summary statistics for these variables are computed by the following statements and presented in [Output 13.1.1](#):

```
proc means data=mylib.CrimeOH;
    var crime income hvalue;
run;
```

Output 13.1.1 Summary Statistics

The MEANS Procedure

Variable	N	Mean	Std Dev	Minimum	Maximum
crime	49	35.1288367	16.7320385	0.1780000	68.8920000
income	49	14.3749388	5.7033781	4.4770000	31.0700000
hvalue	49	38.4362245	18.4660693	17.9000000	96.4000000

The spatial relationships among the 49 neighborhoods are summarized using the first-order neighbor contiguity matrix, contained in the `CrimeWmat` data set. This data set also comes from Anselin (1988).

Spatial Autoregressive (SAR) Model

The following statements fit a spatial autoregressive (SAR) model to the data by using the regressors Income and HValue:

```
/*-- SAR --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
    model crime=income hvalue / type=SAR;
    spatialid sid;
run;
```

In this example, the TYPE=SAR option in the MODEL statement specifies a SAR model. The NONORMALIZE option indicates that the spatial weights data table mylib.CrimeWmat should be used “as is” rather than be row-standardized. The parameter estimates for this model are shown in [Output 13.1.2](#). According to the results, the spatial autoregressive coefficient ρ is positive and significant at the 0.05 level on the basis of the t statistic. This indicates a positive spatial dependence in the data.

Output 13.1.2 Parameter Estimates of SAR Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	45.076368	7.870002	5.73	<.0001
income	1	-1.031514	0.328375	-3.14	0.0017
hvalue	1	-0.265923	0.088211	-3.01	0.0026
_rho	1	0.431032	0.123586	3.49	0.0005
_sigma2	1	95.470316	19.499458	4.90	<.0001

Spatial Durbin Model (SDM)

To fit a spatial Durbin model (SDM), you specify the SPATIALEFFECTS statement and specify the TYPE=SAR option in the MODEL statement or the PROC CSPATIALREG statement. In this example, the spatial lags of the regressors Income and HValue are considered in the SDM.

The following statements fit an SDM to the CrimeOH data:

```
/*-- SDM --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
    model crime=income hvalue / type=SAR;
    spatialeffects income hvalue;
    spatialid sid;
run;
```

The parameter estimates are shown in [Output 13.1.3](#). As in the SAR model, the spatial autoregressive coefficient ρ in the SDM is positive and significant at the 0.05 level on the basis of the t statistic, indicating a positive spatial dependence in the data.

Output 13.1.3 Parameter Estimates of SDM
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	42.802410	13.923873	3.07	0.0021
income	1	-0.914200	0.336418	-2.72	0.0066
hvalue	1	-0.293746	0.088851	-3.31	0.0009
W_income	1	-0.519612	0.594739	-0.87	0.3823
W_hvalue	1	0.245718	0.176843	1.39	0.1647
_rho	1	0.426506	0.167485	2.55	0.0109
_sigma2	1	91.768262	18.904590	4.85	<.0001

To avoid potential collinearity with the intercept term in the MODEL statement, the SPATIALEFFECTS statement always excludes the intercept term. This means that only variables that you explicitly specify in the SPATIALEFFECTS statement are used to construct spatial lag of covariate effects.

Spatial Error Model (SEM)

To fit a spatial error model (SEM), specify the TYPE=SEM option in the MODEL statement or the PROC CSPATIALREG statement.

The following statements fit an SEM to the CrimeOH data:

```

/*-- SEM --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SEM;
  spatialid sid;
  restrict _lambda<0.99;
run;

```

The parameter estimates are shown in [Output 13.1.4](#). According to this output, the p -value for the spatial autocorrelation parameter λ is 0.0002 on the basis of the t statistic. The results indicate a significant positive dependence in the error term.

Output 13.1.4 Parameter Estimates of SEM
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	59.890244	5.882911	10.18	<.0001
income	1	-0.941190	0.370165	-2.54	0.0110
hvalue	1	-0.302255	0.090529	-3.34	0.0008
_lambda	1	0.561879	0.152369	3.69	0.0002
_sigma2	1	95.523372	20.017061	4.77	<.0001

Spatial Durbin Error Model (SDEM)

To fit a spatial Durbin error model (SDEM), use the SPATIALEFFECTS statement and specify the TYPE=SEM option in the MODEL statement or the PROC CSPATIALREG statement. In this example, the spatial lags of the regressors Income and HValue are considered in the SDEM.

The following statements fit an SDEM to the CrimeOH data:

```
/*-- SDEM --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SEM;
  spatialeffects income hvalue;
  spatialid sid;
run;
```

The parameter estimates are shown in [Output 13.1.5](#).

Output 13.1.5 Parameter Estimates of SDEM
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	73.540497	8.860552	8.30	<.0001
income	1	-1.051696	0.322416	-3.26	0.0011
hvalue	1	-0.275607	0.091148	-3.02	0.0025
W_income	1	-1.156543	0.592883	-1.95	0.0511
W_hvalue	1	0.111750	0.202354	0.55	0.5808
_lambda	1	0.425413	0.173824	2.45	0.0144
_sigma2	1	92.521238	19.084926	4.85	<.0001

Spatial Moving Average (SMA) Model

To fit an SMA model, specify the TYPE=SMA option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements fit an SMA model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SMA;
  spatialid sid;
run;
```

The parameter estimates are shown in [Output 13.1.6](#). According to the results, the spatial coefficient λ is negative and significant at the 0.05 level on the basis of the t statistic. This indicates a positive spatial dependence in the errors.

Output 13.1.6 Parameter Estimates of SMA Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	59.252971	5.934861	9.98	<.0001
income	1	-0.921806	0.363482	-2.54	0.0112
hvalue	1	-0.287393	0.086880	-3.31	0.0009
_lambda	1	-0.799089	0.277861	-2.88	0.0040
_sigma2	1	117.731990	26.373322	4.46	<.0001

Spatial Durbin Moving Average (SDMA) Model

To fit an SDMA model, use the SPATIALEFFECTS statement and specify the TYPE=SMA option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements consider the spatial lags of the regressors INCOME and HVALUE and fit an SDMA model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SMA;
  spatialeffects income hvalue;
  spatialid sid;
run;
```

Partial output is shown in [Output 13.1.7](#). According to the results, the spatial coefficient λ is negative and significant at the 0.05 level on the basis of the t statistic. This indicates a positive spatial dependence in the errors.

Output 13.1.7 Parameter Estimates of an SDMA Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	73.944211	9.083977	8.14	<.0001
income	1	-1.065635	0.312045	-3.42	0.0006
hvalue	1	-0.266840	0.092400	-2.89	0.0039
W_income	1	-1.074757	0.584955	-1.84	0.0662
W_hvalue	1	0.067568	0.209867	0.32	0.7475
_lambda	1	-0.642124	0.296638	-2.16	0.0304
_sigma2	1	103.502516	22.487027	4.60	<.0001

Spatial Autoregressive Confused (SAC) Model

To fit an SAC model, specify the TYPE=SAC option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements fit the SAC model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SAC;
  spatialid sid;
  restrict _lambda<0.99;
run;
```

The parameter estimates are shown in [Output 13.1.8](#).

Output 13.1.8 Parameter Estimates of SAC Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	47.778144	9.278161	5.15	<.0001
income	1	-1.025824	0.333984	-3.07	0.0021
hvalue	1	-0.281635	0.093361	-3.02	0.0026
_rho	1	0.368158	0.181115	2.03	0.0421
_lambda	1	0.166521	0.298117	0.56	0.5765
_sigma2	1	95.584355	19.469071	4.91	<.0001

Spatial Durbin Autoregressive Confused (SDAC) Model

To fit an SDAC model, use the SPATIALEFFECTS statement and specify the TYPE=SAC option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements consider the spatial lags of the regressors INCOME and HVALUE and fit an SDAC model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SAC;
  spatialeffects income hvalue;
  spatialid sid;
  restrict _lambda<0.99;
run;
```

The parameter estimates are shown in [Output 13.1.9](#).

Output 13.1.9 Parameter Estimates of SDAC Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	50.908729	31.033511	1.64	0.1009
income	1	-0.950768	0.353881	-2.69	0.0072
hvalue	1	-0.286432	0.091261	-3.14	0.0017
W_income	1	-0.692491	0.839213	-0.83	0.4093
W_hvalue	1	0.208611	0.222514	0.94	0.3485
_rho	1	0.315691	0.413932	0.76	0.4457
_lambda	1	0.154954	0.473634	0.33	0.7435
_sigma2	1	93.184031	19.197723	4.85	<.0001

Spatial Autoregressive Moving Average (SARMA) Model

To fit a SARMA model, specify the TYPE=SARMA option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements fit a SARMA model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SARMA;
  spatialid sid;
run;
```

The parameter estimates are shown in [Output 13.1.10](#).

Output 13.1.10 Parameter Estimates of SARMA Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	48.973247	9.602039	5.10	<.0001
income	1	-1.016359	0.337215	-3.01	0.0026
hvalue	1	-0.287458	0.093079	-3.09	0.0020
_rho	1	0.336281	0.204317	1.65	0.0998
_lambda	1	-0.271945	0.426840	-0.64	0.5241
_sigma2	1	97.992936	21.253768	4.61	<.0001

Spatial Durbin Autoregressive Moving Average (SDARMA) Model

To fit an SDARMA model, use the SPATIALEFFECTS statement and specify the TYPE=SARMA option in the PROC CSPATIALREG statement or the MODEL statement.

The following statements consider the spatial lag of the regressor HVALUE and fit an SDARMA model to the CRIMEOH data:

```
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=SARMA;
  spatialeffects hvalue;
  spatialid sid;
run;
```

The parameter estimates are shown in [Output 13.1.11](#).

Output 13.1.11 Parameter Estimates of SDARMA Model

The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	30.280526	16.779263	1.80	0.0711
income	1	-0.960400	0.332845	-2.89	0.0039
hvalue	1	-0.293353	0.090767	-3.23	0.0012
W_hvalue	1	0.239748	0.206784	1.16	0.2463
_rho	1	0.590709	0.234325	2.52	0.0117
_lambda	1	0.191790	0.455187	0.42	0.6735
_sigma2	1	89.039641	18.819474	4.73	<.0001

Linear Regression Model

To fit a linear model, specify the TYPE=LINEAR option in the MODEL statement or the PROC CSPATIALREG statement.

The following statements fit a linear model to the CrimeOH data:

```
/*-- LINEAR --*/
proc cspatialreg data=mylib.CrimeOH;
  model crime=income hvalue / type=LINEAR;
run;
```

Partial output is shown in [Output 13.1.12](#).

Output 13.1.12 Parameter Estimates of Linear Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	68.618863	4.588210	14.96	<.0001
income	1	-1.597304	0.323739	-4.93	<.0001
hvalue	1	-0.273931	0.099989	-2.74	0.0062
_sigma2	1	122.751696	24.799493	4.95	<.0001

Spatial Lag of X (SLX) Model

To fit a spatial lag of X (SLX) model, use the SPATIALEFFECTS statement and specify the TYPE=LINEAR option in the MODEL statement or the PROC CSPATIALREG statement.

The following statements consider the spatial lags of the regressors Income and HValue and fit an SLX model to the CrimeOH data:

```

/*-- SLX --*/
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeWmat NONORMALIZE;
  model crime=income hvalue / type=LINEAR;
  spatialeffects income hvalue;
  spatialid sid;
run;

```

The parameter estimates are shown in [Output 13.1.13](#).

Output 13.1.13 Parameter Estimates of SLX Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	75.028184	6.279950	11.95	<.0001
income	1	-1.109020	0.354232	-3.13	0.0017
hvalue	1	-0.289734	0.096058	-3.02	0.0026
W_income	1	-1.370866	0.531889	-2.58	0.0100
W_hvalue	1	0.191785	0.189841	1.01	0.3124
_sigma2	1	107.292373	21.676329	4.95	<.0001

Conditional Autoregressive (CAR) Model

The following statements fit a conditional autoregressive (CAR) model to the data by including the two regressors—Income and HValue:

```

/*-- CAR --*/
proc cspatialreg data=mylib.CrimeOH wmat=mylib.CrimeCmat;
  model crime=income hvalue / type=CAR;
  spatialid sid;

```

```
run;
```

In this example, the TYPE=CAR option in the MODEL statement specifies a CAR model. By default, the spatial weights data table mylib.CrimeCmat is row-standardized. The parameter estimates for this model are shown in [Output 13.1.14](#). According to the results, the spatial autoregressive coefficient ρ is positive and significant at the 0.05 level on the basis of the t statistic. This indicates a positive spatial dependence in the data.

Output 13.1.14 Parameter Estimates of CAR Model

The CSPATIALREG Procedure

Parameter Estimates

Example 13.2: Simulated Data Example

Data Description and Objective

This example uses two simulated data sets, SimData and SimW, to illustrate model fitting in PROC CSPATIALREG and to facilitate subsequent discussion.

The SimData data set contains 50 observations and five variables. The variable SID identifies each spatial unit in the data. The three explanatory variables are x1, x2, and x3. The dependent variable is y. The SimW data set defines the spatial contiguity for all 50 spatial units. The first column, SID, in the SimW data set identifies each spatial unit. The remaining entries in the SimW data set are binary and define whether two spatial units are neighbors. A value of 1 indicates that two spatial units are neighbors, and 0 indicates otherwise.

Summary statistics for all variables except SID in the SimData data set are computed by the following statements and presented in [Output 13.2.1](#):

```
proc means data=mylib.SimData;
  var x1 x2 x3 y;
run;
```

Output 13.2.1 Summary Statistics

The MEANS Procedure

Variable	N	Mean	Std Dev	Minimum	Maximum
x1	50	-0.0076329	1.0989504	-2.4523193	1.6539456
x2	50	-0.0829941	0.9671181	-2.5725767	2.4034547
x3	50	-0.0894387	0.9975304	-2.4470049	2.6720533
y	50	1.1569199	1.5687060	-1.9399423	4.7136835

The following statements fit a spatial autoregressive (SAR) model to the data by using three regressors, x1,

x2, and x3:

```
/*-- SAR --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW;
  model y=x1-x3 / type=SAR;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.2.2](#).

Output 13.2.2 Parameter Estimates of SAR Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.780650	0.098703	18.04	<.0001
x1	1	0.573329	0.047395	12.10	<.0001
x2	1	0.707048	0.057181	12.37	<.0001
x3	1	-0.902843	0.053314	-16.93	<.0001
_rho	1	-0.473713	0.063008	-7.52	<.0001
_sigma2	1	0.131509	0.026350	4.99	<.0001

To fit a spatial Durbin model (SDM) that includes exogenous interaction effects of x1, x2, and x3, submit the following statements:

```
/*-- SDM --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW;
  model y=x1-x3/ type=SAR;
  spatialeffects x1-x3;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.2.3](#).

Output 13.2.3 Parameter Estimates of SDM
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.932578	0.198882	9.72	<.0001
x1	1	0.548504	0.049806	11.01	<.0001
x2	1	0.686011	0.056266	12.19	<.0001
x3	1	-0.890161	0.053516	-16.63	<.0001
W_x1	1	0.172302	0.154018	1.12	0.2633
W_x2	1	0.023746	0.198557	0.12	0.9048
W_x3	1	-0.324808	0.228032	-1.42	0.1543
_rho	1	-0.639757	0.164651	-3.89	0.0001
_sigma2	1	0.120527	0.024729	4.87	<.0001

If you want to fit another type of model, you need to change the value of the TYPE= option in the MODEL statement. As an example, to fit a spatial error model (SEM) instead of a SAR model to the data, you can use the following statements:

```
/*-- SEM --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW;
  model y=x1-x3 / type=SEM;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.2.4](#).

Output 13.2.4 Parameter Estimates of SEM
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.166289	0.029514	39.52	<.0001
x1	1	0.487975	0.049086	9.94	<.0001
x2	1	0.634442	0.061776	10.27	<.0001
x3	1	-0.831250	0.054780	-15.17	<.0001
_lambda	1	-0.964826	0.132514	-7.28	<.0001
_sigma2	1	0.147434	0.031318	4.71	<.0001

The following statements fit a spatial autoregressive confused (SAC) model and spatial autoregressive moving average (SARMA) model to the data:

```
/*-- SAC --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW;
  model y=x1-x3 / type=SAC;
  spatialid SID;
run;

/*-- SARMA --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW;
  model y=x1-x3 / type=SARMA;
  spatialid SID;
run;
```

The parameter estimates for the SAC and SARMA models are shown in [Output 13.2.5](#) and [Output 13.2.6](#), respectively.

Output 13.2.5 Parameter Estimates of an SAC Model**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.745140	0.108969	16.01	<.0001
x1	1	0.574630	0.047481	12.10	<.0001
x2	1	0.699848	0.057547	12.16	<.0001
x3	1	-0.909416	0.053365	-17.04	<.0001
_rho	1	-0.449744	0.075425	-5.96	<.0001
_lambda	1	-0.235971	0.277450	-0.85	0.3950
_sigma2	1	0.128845	0.025938	4.97	<.0001

Output 13.2.6 Parameter Estimates of a SARMA Model**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.721937	0.111720	15.41	<.0001
x1	1	0.576752	0.047432	12.16	<.0001
x2	1	0.694100	0.058118	11.94	<.0001
x3	1	-0.910829	0.053061	-17.17	<.0001
_rho	1	-0.434840	0.079844	-5.45	<.0001
_lambda	1	0.393432	0.342912	1.15	0.2512
_sigma2	1	0.133287	0.027984	4.76	<.0001

Example 13.3: Compact Representation of a Spatial Weights Matrix

When a spatial weights matrix is sparse, you might want to provide its compact representation rather than the full matrix to the CSPATIALREG procedure. This example shows you how to use the compact representation of a spatial weights matrix in PROC CSPATIALREG. For illustration, the simulated data sets SimData and SimW from “[Example 13.2: Simulated Data Example](#)” on page 696 are used here. The compact representation of the spatial weights matrix in the SimW data set is created and saved in the data set SimW_Compact.

The first 10 observations in the SimW_Compact data set are shown in [Figure 13.3.1](#).

Output 13.3.1 SimW_Compact Data Set

Obs	SID	cSID	Value
1	L50	L45	1
2	L32	L35	1
3	L50	L25	1
4	L45	L36	1
5	L10	L8	1
6	L44	L48	1
7	L7	L6	1
8	L36	L15	1
9	L5	L19	1
10	L37	L46	1

To fit a spatial autoregressive (SAR) model, you can use the following statements:

```

/*-- SAR --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW_Compact;
  model y=x1-x3 / type=SAR;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.3.2](#).

Output 13.3.2 Parameter Estimates of SAR Model with Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t	
Intercept	1	1.780650	0.098703	18.04	<.0001	
x1	1	0.573329	0.047395	12.10	<.0001	
x2	1	0.707048	0.057181	12.37	<.0001	
x3	1	-0.902843	0.053314	-16.93	<.0001	
_rho	1	-0.473713	0.063008	-7.52	<.0001	
_sigma2	1	0.131509	0.026350	4.99	<.0001	

To fit a spatial error model (SEM) instead of a SAR model to the data, you can use the following statements:

```

/*-- SEM --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW_Compact;
  model y=x1-x3 / type=SEM;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.3.3](#).

Output 13.3.3 Parameter Estimates of SEM with Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.166289	0.029514	39.52	<.0001
x1	1	0.487975	0.049086	9.94	<.0001
x2	1	0.634442	0.061776	10.27	<.0001
x3	1	-0.831250	0.054780	-15.17	<.0001
_lambda	1	-0.964826	0.132514	-7.28	<.0001
_sigma2	1	0.147434	0.031318	4.71	<.0001

If you want to fit another type of model, you need to change the value of the TYPE= option in the MODEL statement. For example, to fit a spatial autoregressive moving average (SARMA) model and a spatial autoregressive confused (SAC) model to the data, you can use the following statements:

```

/*-- SARMA --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW_Compact;
  model y=x1-x3 / type=SARMA;
  spatialid SID;
run;

/*-- SAC --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW_Compact;
  model y=x1-x3 / type=SAC;
  spatialid SID;
run;

```

The parameter estimates for the SARMA and SAC models are shown in [Output 13.3.4](#) and [Output 13.3.5](#), respectively.

Output 13.3.4 Parameter Estimates of a SARMA Model with Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.721937	0.111720	15.41	<.0001
x1	1	0.576752	0.047432	12.16	<.0001
x2	1	0.694100	0.058118	11.94	<.0001
x3	1	-0.910829	0.053061	-17.17	<.0001
_rho	1	-0.434840	0.079844	-5.45	<.0001
_lambda	1	0.393432	0.342912	1.15	0.2512
_sigma2	1	0.133287	0.027984	4.76	<.0001

Output 13.3.5 Parameter Estimates of an SAC Model with Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.745140	0.108969	16.01	<.0001
x1	1	0.574630	0.047481	12.10	<.0001
x2	1	0.699848	0.057547	12.16	<.0001
x3	1	-0.909416	0.053365	-17.04	<.0001
_rho	1	-0.449744	0.075425	-5.96	<.0001
_lambda	1	-0.235971	0.277450	-0.85	0.3950
_sigma2	1	0.128845	0.025938	4.97	<.0001

Example 13.4: Taylor and Chebyshev Approximations

When you have a large data set (that is, the number of spatial units in your data is large), it becomes burdensome to fit some models. This is partly because all models except linear regression models require you to calculate the determinant of the matrix of a large size (such as $|\mathbf{I} - \rho\mathbf{W}|$ in a spatial autoregressive model). In these cases, using Taylor and Chebyshev approximations in the CSPATIALREG procedure can be helpful. PROC CSPATIALREG enables you to estimate spatial autoregressive, spatial Durbin, spatial error, and spatial Durbin error models that have a relatively large spatial weights matrix by using these two approximations. By using the two small data sets SimData and SimW from “[Example 13.2: Simulated Data Example](#)” on page 696, examples in this section show how you can invoke the two approximations in PROC CSPATIALREG.

The following statements fit a spatial autoregressive (SAR) model by using Chebyshev approximation:

```
/*-- SAR Model : full W --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW approximation=(ORDER=10);
  model y=x1-x3 / type=SAR;
  spatialid SID;
run;
```

You use the APPROXIMATION= option to specify which approximation technique to use. By default, Chebyshev approximation is used. The ORDER=10 option specifies a 10th-order Chebyshev polynomial to be used for approximation. The parameter estimates for this model are shown in [Output 13.4.1](#). Note that the spatial weights matrix in the SimW data set is a full matrix. Compared with [Output 13.2.2](#), Chebyshev approximation yields very similar parameter estimates.

Output 13.4.1 Parameter Estimates of SAR Model with Chebyshev Approximation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.780650	0.098703	18.04	<.0001
x1	1	0.573329	0.047395	12.10	<.0001
x2	1	0.707048	0.057181	12.37	<.0001
x3	1	-0.902843	0.053314	-16.93	<.0001
_rho	1	-0.473713	0.063008	-7.52	<.0001
_sigma2	1	0.131509	0.026350	4.99	<.0001

Using the compact representation of the spatial weights matrix, you can submit the following statements to fit a SAR model by using Chebyshev approximation:

```
/*-- SAR Model : compact form of W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW_Compact approximation=(ORDER=10);
  model y=x1-x3 / type=SAR;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.4.2](#), which is identical to [Output 13.4.1](#).

Output 13.4.2 Parameter Estimates of SAR Model with Chebyshev Approximation and Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.780650	0.098703	18.04	<.0001
x1	1	0.573329	0.047395	12.10	<.0001
x2	1	0.707048	0.057181	12.37	<.0001
x3	1	-0.902843	0.053314	-16.93	<.0001
_rho	1	-0.473713	0.063008	-7.52	<.0001
_sigma2	1	0.131509	0.026350	4.99	<.0001

The following statements fit a spatial Durbin model (SDM) by using Taylor approximation. You specify the keyword TAYLOR in the APPROXIMATION= option to request Taylor approximation. In particular, you request a 50th-order Taylor polynomial to be used for approximation by specifying the ORDER=50 option.

```
/*-- SDM : Taylor approximation with full W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW approximation=(Taylor ORDER=50);
  model y=x1-x3 / type=SAR;
  spatialeffects x1-x3;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.4.3](#). Compared with [Output 13.2.3](#), the SDM that is fit using Taylor approximation yields almost identical parameter estimates.

Output 13.4.3 Parameter Estimates of SDM with Taylor Approximation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.932578	0.198882	9.72	<.0001
x1	1	0.548504	0.049806	11.01	<.0001
x2	1	0.686011	0.056266	12.19	<.0001
x3	1	-0.890161	0.053516	-16.63	<.0001
W_x1	1	0.172302	0.154018	1.12	0.2633
W_x2	1	0.023746	0.198557	0.12	0.9048
W_x3	1	-0.324808	0.228032	-1.42	0.1543
_rho	1	-0.639757	0.164651	-3.89	0.0001
_sigma2	1	0.120527	0.024729	4.87	<.0001

With the compact representation, the following statements fit the SDM by using Taylor approximation:

```

/*-- SDM : Taylor approximation with compact W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW_Compact
    approximation=(Taylor ORDER=50);
    model y=x1-x3/ type=SAR;
    spatialeffects x1-x3;
    spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.4.4](#), which is identical to [Output 13.4.3](#).

Output 13.4.4 Parameter Estimates of SDM with Taylor Approximation and Compact Representation**The CSPATIALREG Procedure**

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.932578	0.198882	9.72	<.0001
x1	1	0.548504	0.049806	11.01	<.0001
x2	1	0.686011	0.056266	12.19	<.0001
x3	1	-0.890161	0.053516	-16.63	<.0001
W_x1	1	0.172302	0.154018	1.12	0.2633
W_x2	1	0.023746	0.198557	0.12	0.9048
W_x3	1	-0.324808	0.228032	-1.42	0.1543
_rho	1	-0.639757	0.164651	-3.89	0.0001
_sigma2	1	0.120527	0.024729	4.87	<.0001

To use Chebyshev approximation for the preceding SDM, submit the following statements:

```

/*-- SDM : Chebyshev approximation with full W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW approximation=(ORDER=10);
    model y=x1-x3/ type=SAR;
    spatialeffects x1-x3;
    spatialid SID;

```

```
run;
```

The parameter estimates for this model are shown in [Output 13.4.5](#), which is similar to [Output 13.4.3](#).

Output 13.4.5 Parameter Estimates of SDM with Chebyshev Approximation

The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.932574	0.198876	9.72	<.0001
x1	1	0.548505	0.049806	11.01	<.0001
x2	1	0.686012	0.056266	12.19	<.0001
x3	1	-0.890162	0.053516	-16.63	<.0001
W_x1	1	0.172300	0.154015	1.12	0.2633
W_x2	1	0.023744	0.198554	0.12	0.9048
W_x3	1	-0.324805	0.228027	-1.42	0.1543
_rho	1	-0.639755	0.164646	-3.89	0.0001
_sigma2	1	0.120527	0.024729	4.87	<.0001

To use Chebyshev approximation for this model with compact representation, submit the following statements:

```
/*-- SDM : Chebyshev approximation with compact W --*/
proc cspatialreg data=mylib.SimData wmat=mylib.SimW_Compact approximation=(ORDER=10);
  model y=x1-x3/ type=SAR;
  spatialeffects x1-x3;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.4.6](#).

Output 13.4.6 Parameter Estimates of SDM with Chebyshev Approximation and Compact Representation

The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.932574	0.198876	9.72	<.0001
x1	1	0.548505	0.049806	11.01	<.0001
x2	1	0.686012	0.056266	12.19	<.0001
x3	1	-0.890162	0.053516	-16.63	<.0001
W_x1	1	0.172300	0.154015	1.12	0.2633
W_x2	1	0.023744	0.198554	0.12	0.9048
W_x3	1	-0.324805	0.228027	-1.42	0.1543
_rho	1	-0.639755	0.164646	-3.89	0.0001
_sigma2	1	0.120527	0.024729	4.87	<.0001

The following statements fit a spatial error model (SEM) by using Chebyshev approximation:

```

/*-- SEM : full W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW approximation=(ORDER=10);
  model y=x1-x3 / type=SEM;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.4.7](#). Note that the spatial weights matrix in the mylib.SimW data table is a full matrix. Compared with [Output 13.2.4](#), Chebyshev approximation yields similar parameter estimates.

Output 13.4.7 Parameter Estimates of SEM with Chebyshev Approximation

The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.166221	0.029666	39.31	<.0001
x1	1	0.488222	0.049184	9.93	<.0001
x2	1	0.635419	0.061432	10.34	<.0001
x3	1	-0.831401	0.054913	-15.14	<.0001
_lambda	1	-0.957363	0.117021	-8.18	<.0001
_sigma2	1	0.148034	0.031092	4.76	<.0001

Using the compact representation of the spatial weights matrix, you can submit the following statements to fit an SEM by using Chebyshev approximation:

```

/*-- SEM : compact form of W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW_Compact approximation=(ORDER=10);
  model y=x1-x3 / type=SEM;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.4.8](#), which is almost identical to [Output 13.4.7](#).

Output 13.4.8 Parameter Estimates of SEM with Chebyshev Approximation and Compact Representation

The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	1.166221	0.029666	39.31	<.0001
x1	1	0.488222	0.049184	9.93	<.0001
x2	1	0.635419	0.061432	10.34	<.0001
x3	1	-0.831401	0.054913	-15.14	<.0001
_lambda	1	-0.957363	0.117021	-8.18	<.0001
_sigma2	1	0.148034	0.031092	4.76	<.0001

The following statements fit a spatial Durbin error model (SDEM) by using Taylor approximation:

```

/*-- SDEM : Taylor approximation with full W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW approximation=(Taylor ORDER=50);
  model y=x1-x3/ type=SEM;
  spatialeffects x1-x3;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.4.9](#).

Output 13.4.9 Parameter Estimates of SDEM with Taylor Approximation

The CSPATIALREG Procedure

Parameter Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t	
Intercept	1	1.193178	0.047129	25.32	<.0001	
x1	1	0.566497	0.056782	9.98	<.0001	
x2	1	0.722060	0.059717	12.09	<.0001	
x3	1	-0.909212	0.061286	-14.84	<.0001	
W_x1	1	-0.135284	0.128339	-1.05	0.2918	
W_x2	1	-0.418116	0.152899	-2.73	0.0062	
W_x3	1	0.290041	0.192397	1.51	0.1317	
_lambda	1	-0.723853	0.209844	-3.45	0.0006	
_sigma2	1	0.126723	0.026820	4.73	<.0001	

With the compact representation, the following statements fit the SDEM by using Taylor approximation:

```

/*-- SDEM : Taylor approximation with compact W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW_Compact
  approximation=(Taylor ORDER=50);
  model y=x1-x3/ type=SEM;
  spatialeffects x1-x3;
  spatialid SID;
run;

```

The parameter estimates for this model are shown in [Output 13.4.10](#), which is identical to [Output 13.4.9](#).

Output 13.4.10 Parameter Estimates of SDEM with Taylor Approximation and Compact Representation

The CSPATIALREG Procedure

Parameter Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t	
Intercept	1	1.193178	0.047129	25.32	<.0001	
x1	1	0.566497	0.056782	9.98	<.0001	
x2	1	0.722060	0.059717	12.09	<.0001	
x3	1	-0.909212	0.061286	-14.84	<.0001	
W_x1	1	-0.135284	0.128339	-1.05	0.2918	
W_x2	1	-0.418116	0.152899	-2.73	0.0062	
W_x3	1	0.290041	0.192397	1.51	0.1317	
_lambda	1	-0.723853	0.209844	-3.45	0.0006	
_sigma2	1	0.126723	0.026820	4.73	<.0001	

To use Chebyshev approximation to fit the preceding SDEM, submit the following statements:

```
/*-- SDEM : Chebyshev approximation with full W --*/
proc cspatialreg data=mylib.SimData Wmat=mylib.SimW approximation=(ORDER=10);
  model y=x1-x3/ type=SEM;
  spatialeffects x1-x3;
  spatialid SID;
run;
```

The parameter estimates for this model are shown in [Output 13.4.11](#), which is similar to [Output 13.4.9](#).

Output 13.4.11 Parameter Estimates of SDEM with Chebyshev Approximation

The CSPATIALREG Procedure

Parameter Estimates						
Parameter	DF	Estimate	Standard Error	t Value	Pr > t	Approx
Intercept	1	1.193178	0.047129	25.32	<.0001

Example 13.5: Impact Estimation

Data Description and Objective

Examples in this section use the CrimeOH and CrimeWmat data sets that are described in “[Example 13.1: Columbus Crime Data](#)” on page 687 to demonstrate impact estimation in PROC CSPATIALREG.

Spatial Lag of X (SLX) Model

The following statements fit a spatial lag of X (SLX) model to the data by using Income and HValue as explanatory variables, and they estimate the average direct impacts, the average indirect impacts, and the average total impacts for these two explanatory variables.

```

/*-- SLX --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat impact(nmc=1000);
  model crime=income hvalue / type=LINEAR;
  spatialeffects income hvalue;
  spatialid sid;
run;

```

In this example, the TYPE=LINEAR option in the MODEL statement and SPATIALEFFECTS statement specify an SLX model. The IMPACT option requests that the average direct impacts, the average indirect impacts, and the average total impacts be computed for explanatory variables in the model. The impact estimates for this model are shown in [Output 13.5.2](#). According to [Output 13.5.2](#), Income has a direct impact of -1.11 and an indirect impact of -1.37 on Crime, which equal the coefficient estimate of Income and the spatial lag of Income, respectively, in [Output 13.5.1](#). Similarly, HValue has a direct impact of -0.29 and an indirect impact of 0.19 on Crime, which equal the coefficient estimate of HValue and the spatial lag of HValue, respectively, in [Output 13.5.1](#).

Output 13.5.1 Parameter Estimates of the SLX Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	75.028374	6.278808	11.95	<.0001
income	1	-1.108925	0.354227	-3.13	0.0017
hvalue	1	-0.289729	0.096056	-3.02	0.0026
W_income	1	-1.370974	0.531869	-2.58	0.0099
W_hvalue	1	0.191771	0.189837	1.01	0.3124
_sigma2	1	107.287543	21.675353	4.95	<.0001

Output 13.5.2 Impact Estimates of Regressors in the SLX Model

Impact Estimates Summary								
Parameter	Direct			Indirect			Total	
	Mean	Standard Deviation	t Value	Mean	Standard Deviation	t Value	Mean	Standard Deviation
income	-1.108925	0.354227	-3.13	-1.370974	0.531869	-2.58	-2.479899	0.470529
hvalue	-0.289729	0.096056	-3.02	0.191771	0.189837	1.01	-0.097958	0.192176

Spatial Error Model (SEM)

The following statements fit an SEM model to the data by using Income and HValue as two explanatory variables, and they estimate impacts for these two variables:

```

/*-- SEM --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat impact(nmc=10000);
    model crime=income hvalue / type=SEM;
    spatialid sid;
run;

```

In this example, the TYPE=SEM option in the MODEL statement specifies an SEM model. The IMPACT option requests that the average direct impacts, the average indirect impacts, and the average total impacts be computed for explanatory variables in the model. The impact estimates for this model are shown in [Output 13.5.4](#). According to the results, both Income and HValue have direct impacts but not indirect impacts on the dependent variable Crime. Moreover, the direct impacts of Income and HValue equal their coefficient estimates in [Output 13.5.3](#).

Output 13.5.3 Parameter Estimates of the SEM Model
The CSPATIALREG Procedure

Parameter Estimates					
Parameter	DF	Estimate	Standard Error	t Value	Approx Pr > t
Intercept	1	59.914436	5.881216	10.19	<.0001
income	1	-0.942892	0.370508	-2.54	0.0109
hvalue	1	-0.302218	0.090549	-3.34	0.0008
_lambda	1	0.560314	0.152809	3.67	0.0002
_sigma2	1	95.554137	20.025909	4.77	<.0001

Output 13.5.4 Impact Estimates of Regressors in the SEM Model

Impact Estimates Summary								
Parameter	Direct			Indirect			Total	
	Mean	Standard Deviation	t Value	Mean	Standard Deviation	t Value	Mean	Standard Deviation
income	-0.942892	0.370508	-2.54	0	0	.	-0.942892	0.370508
hvalue	-0.302218	0.090549	-3.34	0	0	.	-0.302218	0.090549

Spatial Autoregressive (SAR) Model

The following statements fit a SAR model to the data by using the explanatory variables Income and HValue, and they request that the average direct impacts, the average indirect impacts, and the average total impacts be computed for the two explanatory variables:

```

/*-- SAR --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat
  impact(nmc=50000 order=100);
  model crime=income hvalue / type=SAR;
  spatialid sid;
run;

```

The impact estimates for this model are shown in [Output 13.5.5](#). On one hand, you see that Income exerts a negative direct and indirect impact on the number of crimes. This suggests that you would see a decrease in the number of crimes in neighborhoods that have higher incomes. Moreover, increased Income in nearby neighborhoods has a negative impact on the number of crimes. On the other hand, HValue exerts a negative direct impact on the number of crimes. This suggests that you would see a decrease in the number of crimes in neighborhoods that have higher housing values.

Output 13.5.5 Impact Estimates of Regressors in the SAR Model
The CSPATIALREG Procedure

Impact Estimates Summary								
Parameter	Direct			Indirect			Total	
	Mean	Standard Deviation	t Value	Mean	Standard Deviation	t Value	Mean	Standard Deviation
income	-1.091669	0.332260	-3.29	-0.751319	0.372889	-2.01	-1.842988	0.565408
hvalue	-0.282143	0.094550	-2.98	-0.209330	0.141523	-1.48	-0.491473	0.211251

Spatial Durbin Model (SDM)

The following statements fit an SDM model to the data by using the explanatory variables Income and HValue, and they estimate impacts for these two variables:

```
/*-- SDM --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat
  impact(nmc=50000 order=100);
  model crime=income hvalue / type=SAR;
  spatialeffects income hvalue;
  spatialid sid;
run;
```

In this example, the TYPE=SAR option in the MODEL statement specifies a SAR model. The SPATIALEFFECTS statement requests that the spatial lag of explanatory variables Income and HValue be included in the model. The IMPACT option requests that the average direct impacts, the average indirect impacts, and the average total impacts be computed for explanatory variables in the model. To estimate impacts, the NMC= option specifies 50,000 iterations of Monte Carlo simulation and the ORDER= option specifies 100 as the order of Neumann series. The impact estimates for this model are shown in [Output 13.5.6](#). On one hand, you see that the indirect impact of Income is not significant at the 5% significance level (because the *t* value of -1.58 is greater than -1.96). However, the direct impact of Income is negative and significant, suggesting that you would see a decrease in the number of crimes in neighborhoods that have higher incomes. Similarly, HValue exerts a negative direct impact on the number of crimes. This suggests that you would see a decrease in the number of crimes in neighborhoods that have higher housing values.

Output 13.5.6 Impact Estimates of Regressors in the SDM Model
The CSPATIALREG Procedure

Parameter	Impact Estimates Summary								
	Direct			Indirect			Total		
	Mean	Standard Deviation	t Value	Mean	Standard Deviation	t Value	Mean	Standard Deviation	t Value
income	-1.021846	0.329139	-3.10	-1.493714	0.945050	-1.58	-2.515560	1.008252	-2.49
hvalue	-0.278730	0.093730	-2.97	0.201998	0.368789	0.55	-0.076733	0.406750	-0.19

Example 13.6: Comparison of Multiple Models

Data Description and Objective

Example in this section uses the CrimeOH and CrimeWmat data sets that are described in “[Example 13.1: Columbus Crime Data](#)” on page 687 to demonstrate fitting and comparison of multiple models in PROC CSPATIALREG.

Comparison of Multiple Models

The following statements fit multiple models to the CrimeOH and CrimeWmat data sets, which are described in “[Example 13.1: Columbus Crime Data](#)” on page 687, using the regressors Income and HValue:

```
/*-- TYPE=AUTO --*/
proc cspatialreg data=mylib.CrimeOH Wmat=mylib.CrimeWmat;
  model crime=income hvalue / type=AUTO;
  spatialid sid;
run;
```

In this example, the TYPE=AUTO option is specified in the MODEL statement to fit seven models—SAC, SARMA, SAR, SEM, SMA, CAR, and LINEAR. However, the CAR model is not fitted because the input spatial weights matrix **W** is not symmetric. The parameter estimates for the six remaining models—SAC, SARMA, SAR, SEM, SMA, and LINEAR—are shown in [Output 13.6.1](#). The comparison of these six models is provided in [Output 13.6.2](#). If AIC is used for model comparison, [Output 13.6.2](#) suggests that the SAR model is the best model among the six candidate models, because its AIC value is the smallest.

Output 13.6.1 Parameter Estimates of Multiple Models
The CSPATIALREG Procedure

Parameter Estimates

Overview: CSSM Procedure

State space models (SSMs) are used for analyzing continuous response variables that are recorded sequentially according to a numeric indexing variable. In many cases, the indexing variable is time and the observations are collected at regular time intervals—for example, hourly, weekly, or monthly. In such cases, the resulting data are called time series data. In other cases, the indexing variable might not be time or the observations might not be equally spaced according to the indexing variable. These more general types of sequential data are called longitudinal data. Because of their sequential nature, these types of data exhibit some characteristic features. For example, chronologically closer measurements tend to be highly correlated while measurements farther apart are essentially uncorrelated. Data can be trending in a particular direction and can have seasonal or other periodic patterns. SSMs are specially designed to model such sequential data. They apply to both univariate and multivariate response situations and can easily incorporate predictor (independent variable) information when it is available.

The CSSM procedure performs state space modeling of univariate and multivariate time series and longitudinal data. You can do the following with the CSSM procedure:

- analyze quite general linear state space models
- use an expressive language to specify an SSM. An SSM specification consists of specifying a variety of matrices—for example, the state transition matrix and the covariance matrices of the state and observation disturbances. The CSSM procedure provides language similar to a DATA step for specifying the

elements of these matrices. The matrix elements can be user-defined functions of data variables and unknown parameters.

- easily specify several commonly needed univariate and multivariate SSMs by using only a few keywords. These SSMs include the principal univariate and multivariate structural models for regularly spaced data and a variety of trend and cycle models for the longitudinal data.
- estimate unknown model parameters by (restricted) maximum likelihood. The likelihood function is computed by using the (diffuse) Kalman filter algorithm.
- print, or output to a data set, the series forecasts, residuals, and the full-sample estimates of any linear combination of the underlying state variables. These estimates are obtained by using the (diffuse) Kalman filter and smoother algorithm.
- generate residual diagnostic plots and plots useful for detecting structural breaks
- create a score store, a binary large object (BLOB) table, that can be subsequently used for efficient, model-based scenario analysis and for scoring new observations
- using the simulation smoothing algorithm, simulate the latent states conditional on the observed data. This helps generate the sampling distribution of arbitrarily complex functions of the latent states.

PROC CSSM Compared with PROC SSM

PROC CSSM is the CAS version of PROC SSM. This means that it requires SAS Cloud Analytic Services (CAS) in order to run. Except for this difference, PROC CSSM and PROC SSM are identical in their modeling capabilities. Because it works in the cloud environment, PROC CSSM enables you to efficiently handle large numbers of BY groups by exploiting all the available cores and concurrent threads to process them in parallel. The scoring features that are provided by the [SCORE](#) statement and the simulation smoothing features that are provided by the [SIMSMOOTH](#) statement are new in PROC CSSM version 2024.11 and are not available in PROC SSM. These two procedures share virtually identical syntax and should produce essentially identical output. However, there are some important differences between them that arise mainly because CAS tables do not use observation order:

- The ID statement is required in PROC CSSM; it is optional in PROC SSM.
- In cases where multiple observations can have the same ID value, such as in panel data settings, you must use the new [OBSINDEX](#) statement to ensure the reproducibility of the computations. The ID variable together with the OBSINDEX variable uniquely indexes each observation within a BY group.

Background

State space models are widely used in a variety of fields, such as engineering, statistics, econometrics, and agriculture. There are numerous references that deal with state space modeling, particularly with the state space modeling of time series data. State space modeling of longitudinal data has received a little less attention. The primary reference for the modeling techniques implemented in the CSSM procedure is Harvey (1989), which contains treatments of both the time series and longitudinal data. Other useful books about this subject are Pelagatti (2015); Durbin and Koopman (2012); Jones (1993), and Anderson and Moore (1979). In addition, informative articles about state space modeling of longitudinal data include Wecker and Ansley (1983); Kohn and Ansley (1991); De Jong and Mazzi (2001); Eubank, Huang, and Wang (2003), and Selukar (2015). For the implementation details of the diffuse Kalman filter and smoother (the main computational tool used by the CSSM procedure), the main references are a series of articles (De Jong 1989, 1991; De Jong and Chu-Chun-Lin 2003) and the references therein.

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);  
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;  
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section [“Introduction to Shared Concepts”](#) on page 54 in Chapter 4, [“Shared Concepts.”](#)

Getting Started: CSSM Procedure

This example illustrates how you can use the CSSM procedure to analyze a panel of time series. The following data set, *Cigar*, contains information about yearly per capita cigarette sales for 46 geographic regions in the United States over the period 1963–1992. The variables *lsales*, *lprice*, *lndi*, and *lpimin* denote the per capita cigarette sales, price per pack of cigarettes, per capita disposable income, and minimum price in adjoining regions per pack of cigarettes, respectively (all in the natural log scale). The variable *year* contains the observation year, and the variable *region* contains an integer between 1 to 46 that serves as the unique identifier for the region. For additional data description see Baltagi and Levin (1992); Baltagi (1995).

```
data cigar;
  input year region lsales lprice lndi lpimin;
  label lsales = 'Log cigarette sales in packs per capita';
  label lprice = 'Log price per pack of cigarettes';
  label lndi = 'Log per capita disposable income';
  label lpimin = 'Log minimum price in adjoining regions
                 per pack of cigarettes';
  year = intnx( 'year', '1jan63'd, year-63 );
  format year year.;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037
63 4 4.95583 3.23080 7.9288 3.17388
63 5 5.05114 3.28840 7.9772 3.26576

... more lines ...
```

The following statements load the *Cigar* data into the table *mylib.Cigar*:

```
/* Load data into mylib */
data mylib.Cigar;
  set Cigar;
run;
```

The goal of the analysis is to study the impact of the regressors on the smoking behavior and to understand the changes in the smoking patterns in different regions over the years. Consider the following model for *lsales*:

$$\text{lsales}_{i,t} = \mu_{i,t} + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \epsilon_{i,t}$$

This model represents *lsales* in a region *i* and in a year *t* as a sum of region-specific trend components $\mu_{i,t}$, the regression effects due to *lprice*, *lndi*, and *lpimin*, and the observation noise $\epsilon_{i,t}$. Different variations of this model are obtained by considering different models for the trend component $\mu_{i,t}$. Proper modeling of the trend component is important because it captures differences between the regions that result from unrecorded factors such as demographic changes over time, results of anti-smoking campaigns, and so on. The following statements specify and fit one such model:

```

proc cssm data=mylib.Cigar plots=residual;
  id year interval=year;
  obsindex region;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;
  irregular wn;
  model lsales = lprice lndi lpimin IrwTrend wn;
  eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
  output out=mylib.forCigar pdv press;
run;

```

The PROC CSSM statement specifies the input table, `mylib.Cigar`, which contains analysis variables such as the response variable, `lsales`, and the predictor variables, `lprice`, `lndi`, and `lpimin`. The `PLOTS=RESIDUAL` option in the PROC CSSM statement produces residual diagnostic plots. The `ID` statement specifies a numeric index variable (often a SAS date or datetime variable), which is `year` in this case. The `INTERVAL=YEAR` option in the `ID` statement indicates that the measurements are collected yearly. In this example, the `ID` variable (`year`) by itself is not enough to uniquely index each observation in the input table. In such cases, in order to ensure the repeatability of the analysis, you must supply a variable by using the `OBSINDEX` statement (`obsindex region;`) that, together with the `ID` variable, uniquely indexes each observation in the input table.

The next few statements define a 46-dimensional array of dummy variables, `RegionArray`, such that `RegionArray[i]` is 1 if region is i and is 0 otherwise. The next three statements, `TREND`, `IRREGULAR`, and `MODEL`, constitute the model specification part of the program:

- `trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;` defines a trend, named `IrwTrend`, of local linear type (which is signified by the keyword `11` used within the parenthesis after the name). A local linear trend—a trend with time-varying level and time-varying slope—depends on two parameters: the disturbance variance of the level equation and the disturbance variance of the slope equation (see the section “[Local Linear Trend](#)” on page 776 for more information). The `LEVELVAR=0` specification fixes the disturbance variance of the level equation to 0, which results in a trend model called an *integrated random walk* (IRW). An IRW model tends to produce a smoother trend than a general local linear trend. In the limiting case, if the disturbance variance of the slope equation is also 0, the IRW trend reduces to a straight line (with a fixed intercept and slope). In addition, because of the use of the 46-dimensional array, `RegionArray`, in the `CROSS=` option (`cross(matchparm)=(RegionArray)`), this trend specification amounts to fitting a separate IRW trend for each region. This is because, as a result of the `CROSS=` option, `IrwTrend` is treated as a linear combination of 46 (the number of variables in `RegionArray`) stochastically independent, integrated random walks,

$$\text{IrwTrend}_t = \sum_{i=1}^{46} \text{RegionArray}[i] \mu_{i,t}$$

where each $\mu_{i,t}$ is an integrated random walk. Note that since `RegionArray[i]` is a binary variable, `IrwTrend` equals $\mu_{i,t}$ when region is i . Lastly, the use of `MATCHPARM` option specifies that the different IRW trends $\mu_{i,t}$ use the same disturbance variance parameter for their slope equation. This is

done mainly for parsimony. Based on the model diagnostics shown later, this appears to be a reasonable model simplification.

- **irregular wn**; defines the observation noise $\epsilon_{i,t}$, named **wn**, as a sequence of independent, identically distributed, zero-mean, Gaussian variables—a white noise sequence.
- **model lsales = lprice lndi lpimin lrwTrend wn**; defines the model for **lsales** as a sum of regression effects that involve **lprice**, **lndi**, and **lpimin**, a trend term, **lrwTrend**, and the observation noise **wn**.

The last two statements, **EVAL** and **OUTPUT**, control certain aspects of the procedure output. The following **EVAL** statement defines a linear combination, named **TrendPlusReg**, of selected terms in the **MODEL** statement:

```
eval TrendPlusReg = lrwTrend + lprice + lndi + lpimin;
```

This **EVAL** statement causes the CSSM procedure to produce an estimate of **TrendPlusReg** (and its standard error), which can then be printed or output to a data set. **TrendPlusReg** contains all the terms in the model except for the observation noise and thus can be regarded as the *explanatory* part of the model. In the **OUTPUT** statement, you can specify an output data set that stores all the component estimates that are produced by the procedure. The following **OUTPUT** statement specifies **mylib.forCigar** as the output data set:

```
output out=mylib.forCigar pdv press;
```

The **PDV** option causes variables such as **region1**–**region46**, which are defined by the **DATA** step statements within the CSSM procedure, also to be included in the output data set. The **PRESS** option causes the printing of fit measures that are based on the delete-one cross validation errors (see the section “[Delete-One Cross Validation and Structural Breaks](#)” on page 773 for more information).

All the models that are specified in the CSSM procedure possess a state space representation. For more information, see the section “[State Space Model and Notation](#)” on page 760. The CSSM procedure output begins with a table (not shown here) of the input data set that provides the name and other information. Next, the “Model Summary” table, shown in [Figure 14.1](#), provides basic model information, such as the following:

- the dimension of the underlying state equation, 92 (because each of the 46 IRW trends $\mu_{i,t}$ contributes two elements to the state)
- the diffuse dimension of the model, 95 (which is equal to the three regressors plus the 92 diffuse initial states of $\mu_{i,t}$)
- the number of model parameters, 2 (which is the common disturbance variance of the slope equation in **lrwTrend** and the variance of the noise term **wn**)

This information is very useful in determining the computational complexity of the model (the larger state size, 92, explains the relatively long computing time—as much as two minutes on some desktops—for this example).

Figure 14.1 Summary of the Underlying State Space Model

Model Summary	
Number of Model Equations	1
State Dimension	92
Dimension of the Diffuse Initial Condition	95
Number of Parameters	2

The index variable information is shown in Figure 14.2. Among other things, it categorizes the data to be of the type *Regular with Replication*, which implies that the data are regularly spaced with respect to the ID variable and at least some observations have the same ID value. This is clearly true in this example: the data are yearly without any gaps, and there are 46 observations in each year—one per region.

Figure 14.2 Index Variable Information

ID Variable Information					
Maximum Distinct					
Name	Start	End	Delta	Values	Type
year	1963	1992	1.0000	30	Regular with Replication

Figure 14.3 provides simple summary information about the response variable. It shows that *Isales* has no missing values and no induced missing values because the predictors in the model, *lprice*, *Indi*, and *lpimin*, do not have any missing values either.

Figure 14.3 Response Variable Summary

Response Variable Information							
Number of Observations							
		Induced		Standard			
Name	Total	Missing	Missing	Minimum	Maximum	Mean	Deviation
Isales	1380	0	0	3.978	5.697	4.793	0.2246

The regression coefficients of *lprice*, *Indi*, and *lpimin* are shown in Figure 14.4. As expected, the coefficient of *lprice* is negative and the coefficients of *Indi* and *lpimin* are positive, all being statistically significant. This is consistent with the expectation that the cigarette sales are adversely affected by the price and are positively correlated with the disposable income. The estimated effect of *lpimin*, called the bootlegging effect by Baltagi and Levin (1992), is statistically significant but smaller than the effects of *lprice* and *Indi*.

Figure 14.4 Estimated Regression Coefficients

Regression Parameter Estimates					
		Standard			
Response	Regressor	Estimate	Error	t Value	Pr > t
Isales	lprice	-0.3480	0.0232	-15.01	<.0001
Isales	Indi	0.1425	0.0344	4.15	<.0001
Isales	lpimin	0.0619	0.0269	2.30	0.0214

Figure 14.5 Estimated Model Parameters

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
lrwTrend	LL Trend	Slope Variance	0.0002	0.0000	7.72
wn	Irregular	Variance	0.0006	0.0000	17.29

Figure 14.5 shows the estimates of the disturbance variance of the slope equation in lrwTrend and the variance of the noise term wn.

Figure 14.6 shows a panel of residual normality diagnostic plots. These plots show that the residuals are symmetrically distributed but contain slightly larger than expected number of extreme residuals. Figure 14.7 shows the plot of residuals versus time. There the residuals do not exhibit any obvious pattern; however, the plot does show that more extreme residuals appear before 1970 and after 1989. On the whole, however, these plots do not exhibit serious violations of model assumptions.

Figure 14.6 Residual Normality Check

Figure 14.7 Standardized Residuals Plotted against Time

Figure 14.8 shows the details of the likelihood computations such as the number of nonmissing response values used and the likelihood of the fitted model. For more information, see the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769. Figure 14.8 shows the likelihood-based information criteria in lower-is-better format, which are useful for model comparison.

Figure 14.8 Likelihood Computation Details

Likelihood Computation Summary	
Nonmissing Response Values Used	1380
Estimated Parameters	2
Initialized Diffuse State Elements	95
Normalized Residual Sum of Squares	1285
Diffuse Log Likelihood	2246
Profile Log Likelihood	2170

Figure 14.9 Information Criteria

Information Criteria		
Statistic	Diffuse Likelihood	Profile Likelihood
AIC (lower is better)	-4488	-4145
BIC (lower is better)	-4478	-3638
AICC (lower is better)	-4488	-4130
HQIC (lower is better)	-4484	-3955
CAIC (lower is better)	-4476	-3541

In addition to the regression estimates, it is useful to analyze the estimates of different model components such as the trend component `lrwTrend` and the linear combination `TrendPlusReg`. These estimates can be printed by using the `PRINT=` option provided in the `TREND` and `EVAL` statements, or they can be output to a data set (as it is done in this illustration). This latter option is particularly useful for graphical exploration of these components by standard graphical procedures such as `SGPLOT` and `SGPANEL` procedures. The following statements produce a panel of plots that shows how well the proposed model fits the observed cigarette sales in the first three regions, which correspond to Alabama, Arizona, and Arkansas. The output data set, `mylib.forCigar`, contains all the needed information: `Smoothed_TrendPlusReg` contains the smoothed (full-sample) estimate of `TrendPlusReg`, and `Smoothed_Lower_TrendPlusReg` and `Smoothed_Upper_TrendPlusReg` contain its 95% lower and upper confidence limits. In addition, for easy readability, a user-defined format (`RegionFormat`), which is created by using the `FORMAT` procedure (not shown), is used to associate the region names to region values.

```
proc sgpanel data=mylib.forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Sales Patterns with 95% Confidence Band';
  panelby region / columns=3;
  band x=year lower=Smoothed_Lower_TrendPlusReg
  upper=Smoothed_Upper_TrendPlusReg;
  scatter x=year y=lsales;
  series x=year y= Smoothed_TrendPlusReg;
run;
```

Figure 14.10 Cigarette Sales Patterns for the First Three Regions

Figure 14.10 seems to indicate that the model fits the data reasonably well. It also shows that Arizona differs markedly from Alabama and Arkansas in its cigarette sales pattern over the years. The following statements produce a similar panel of plots that show the estimate of trend without the regression effects:

```
proc sgpanel data=mylib.forCigar noautolegend;
  where region <= 3;
  format region RegionFormat.;
  title 'Region-Specific Trend Estimates';
  panelby region / columns=3;
  series x=year y= smoothed_IrwTrend;
run;
```

Figure 14.11 Estimate of $lrwTrend$ for the First Three Regions

The trend patterns, shown in Figure 14.11, seem to suggest that after accounting for the regression effects, per capita cigarette sales were on the rise in Alabama and Arkansas while they were declining in Arizona.

Syntax: CSSM Procedure

The following statements are available in the CSSM procedure:

```

PROC CSSM < options > ;
  BY variables ;
  COMPONENT name = (variables) * state < / options > ;
  DEPLAG name(response-variable) lag-term1 < lag-term2 ... > ;
  DISPLAY < table-list > < / options > ;
  DISPLAYOUT table-spec-list < / options > ;
  EVAL name = expression < / options > ;
  ID variable < option > ;
  IRREGULAR name < options > ;
  MODEL response = variables < / options > ;
  OBSINDEX variable ;
  OUTPUT < options > ;
  PARMS variables < / options > ;
  Programming statements ;
  SCORE options ;
  SIMSMOOTH options ;
  STATE name(dim)< options > ;
  TREND name(type)< options > ;

```

You can specify all statements multiple times, except the BY, ID, OBSINDEX, OUTPUT, SCORE, and SIMSMOOTH statements. The PROC CSSM statement, the ID statement, and at least one MODEL statement are required. An exception to this rule is during scoring and simulation smoothing. In that case, only the PROC CSSM statement, BY statement (when applicable), and SCORE statement (for scoring) or SIMSMOOTH statement (for simulation smoothing) are required. In addition to these statements, you can use most DATA step programming statements to define new variables that are needed for specifying different parts of the state space model.

NOTE: In the statement options described throughout this section, whenever you use a list to specify the elements of the system matrices, the list elements must all be of the same type: either all of them must be variables or all of them must be numbers. In addition, if the list contains more than one variable, then they cannot be of the array type. These are not serious restrictions. When the list contains mix of variables and numbers, you can redefine the numbers as constant variables. Similarly, you can reformulate a list that contains a mix of variables of array and non-array types as just one array by combining all its elements in a new array.

Functional Summary

Table 14.1 summarizes the statements and options that control the CSSM procedure. Most commonly needed scenarios are listed; for more information, see the individual statements.

Table 14.1 PROC CSSM Functional Summary

Description	Statement	Option
Data Set Options		
Specifies the input data set	PROC CSSM	DATA=
Writes series and component forecasts to an output data set	OUTPUT	OUT=
Model Specification Options		
Specifies the index variable	ID	
Defines variables as model parameters	PARMS	
Specifies a response variable and the associated observation equation	MODEL	
Specifies a state subsection	STATE	
Specifies the transition matrix of a state subsection	STATE	T
Specifies the disturbance covariance matrix of a state subsection	STATE	COV
Specifies the size of the diffuse initial condition of a state subsection	STATE	A1
Specifies the initial covariance matrix of a state subsection	STATE	COV1
Specifies a state subsection for a predefined structural model	STATE	TYPE=
Specifies the regressors in a state equation	STATE	W
Specifies the input vector in a state equation	STATE	SINPUT=
Specifies a component	COMPONENT	
Specifies a predefined trend component	TREND	
Likelihood Optimization Process Control Options		
Specifies the optimization technique	PROC CSSM	OPTIMIZER(TECH=)
Limits the number of iterations	PROC CSSM	OPTIMIZER(MAXITER=)
Outlier and Structural Break Detection Options		
Turns on the search for additive outliers (AO)		Default
Turns on the search for structural breaks in a state subsection	STATE	CHECKBREAK
Turns on the search for structural breaks in a state subsection associated with a trend	TREND	CHECKBREAK
Specifies the significance level for additive outlier tests	OUTPUT	AO(ALPHA=)

Table 14.1 *continued*

Description	Statement	Option
Limits the reported number of additive outliers	OUTPUT	AO(MAXNUM=)
Limits the reported number of additive outliers to a percentage of the series length	OUTPUT	AO(MAXPCT=)
Specifies the significance level for structural break tests	OUTPUT	BREAK(ALPHA=)
Limits the reported number of structural breaks	OUTPUT	BREAK(MAXNUM=)
Limits the reported number of structural breaks to a percentage of the series length	OUTPUT	BREAK(MAXPCT=)
Turns on the search for maximal state shock	OUTPUT	MAXSHOCK
Graphical Residual and Outlier Analysis Options		
Creates a panel of plots that consists of residual normality plots	PROC CSSM	PLOTS=RESIDUAL(NORMAL)
Creates the standardized residual plot against time	PROC CSSM	PLOTS=RESIDUAL(STD)
Creates a panel of plots that consists of prediction error normality plots	PROC CSSM	PLOTS=AO(NORMAL)
Creates the standardized prediction error plot against time	PROC CSSM	PLOTS=AO(STD)

Specifies BY-group processing	BY	

PROC CSSM Statement

PROC CSSM <options> ;

The PROC CSSM statement is required. You can specify the following *options* in the PROC CSSM statement:

BREAKPEAKS

prints an alternate form of the break summary tables when the CHECKBREAK option is used in the **STATE** or **TREND** statement or when the MAXSHOCK option is used in the **OUTPUT** statement. In this alternate form, the summary tables report the significant peaks of the shock statistics curves; see “[Example 14.8: Diagnostic Plots and Structural Break Analysis](#)” on page 841 for examples of these curves.

DATA=*libref.data-table*

names the input data table for PROC CSSM to use. *libref.data-table* is a two-level name, where

<i>libref</i>	refers to a collection of information that is defined in the LIBNAME statement and includes the library, which includes a path to the data, and a session identifier, which defaults to the active session but which can be explicitly defined in the LIBNAME statement. For more information about <i>libref</i> , see the section “ Using CAS Sessions and CAS Engine Librefs ” on page 721.
<i>data-table</i>	specifies the name of the input data table.

LIKE=DIFFUSE | MARGINAL

specifies the type of likelihood to use for parameter estimation. You can specify the following values:

DIFFUSE	specifies diffuse likelihood.
MARGINAL	specifies marginal likelihood.

By default, LIKE=DIFFUSE. For more information about different likelihood types, see the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769.

NOPRINT

turns off all the printing and plotting for the procedure. Any subsequent print options are ignored.

OPTIMIZER(< TECHNIQUE=*technique* > < HESSTYPE=*Hessian-type* > < MAXITER=*integer* >)

specifies options that are associated with the optimizer used in the maximum likelihood parameter estimation. The default settings of the optimization process are adequate for most problems. However, in some cases it might be useful to change the optimization technique, the Hessian type, or the maximum number of iterations. You can specify one of the following *techniques*:

ACTIVESET	uses the active-set method.
DBLDOG	uses the double-dogleg method.
INTERIORPOINT	uses the primal-dual interior point method.
IPDIRECT	uses the primal-dual interior point augmented Lagrangian method.
NEWRAP	uses the Newton-Raphson method.
QUANEW	uses the (dual) quasi-Newton method.
TRUREG	uses the trust region method.

By default, TECHNIQUE=TRUREG. If the technique is ACTIVESET, INTERIORPOINT, or IPDIRECT, you can specify one of the following *Hessian-types*:

BFGS	uses the quasi-Newton Broyden-Fletcher-Goldfarb-Shanno (BFGS) Hessian approximation.
FULL	uses the full Hessian.
SR1	uses the dense quasi-Newton symmetric rank 1 (SR1) Hessian approximation.

By default, HESSTYPE=FULL. The ACTIVESET, INTERIORPOINT, and IPDIRECT techniques and the Hessian types are documented in Chapter 10, “The Nonlinear Programming Solver” ([SAS/OR User’s Guide: Mathematical Programming](#)). The remaining techniques are documented in Chapter 6, “Nonlinear Optimization Methods” ([SAS/ETS User’s Guide](#)). You can alter the maximum number of iterations in the nonlinear optimization search by specifying a nonnegative *integer* as the MAXITER= value.

PLOTS <(global-plot-options)> = plot-request <(options)>

PLOTS<(global-plot-options)> = (plot-request <(options)> <...plot-request <(options)> >)

controls the plots produced with ODS Graphics. When you specify only one *plot-request*, you can omit the parentheses around it. Here are some examples:

```
plots=none
plots=all
plots=residual
plots=residual(normal)
plots=(maxshock residual(normal))
plots(unpack)=residual
```

If you do not specify any specific *plot-request*, then by default PROC CSSM produces the plot of standardized residuals against time. For general information about ODS Graphics, see Chapter 24, “Statistical Graphics Using ODS” (*SAS/STAT User’s Guide*).

Global Plot Options

The *global-plot-options* apply to all relevant plots generated by the CSSM procedure. The following *global-plot-option* is supported:

UNPACK

displays each graph separately. (By default, some graphs can appear together in a single panel.)

Specific Plot Options

The following list describes the specific *plot-requests* and their *options*:

ALL

produces all plots appropriate for the particular analysis.

AO< (prediction-error-plot-options)>

produces the prediction error plots—one for each response variable. You can specify the following *prediction-error-plot-options*:

NORMAL

produces a summary panel of the prediction error diagnostics, which consist of the following:

- histogram of prediction errors
- normal quantile plot of prediction errors

STD

produces a scatter plot of standardized prediction errors against time.

MAXSHOCK

produces a scatter plot of maximal state shock statistics against time.

NONE

suppresses all plots.

RESIDUAL <(residual-plot-options)>

produces the residuals plots—one for each response variable. You can specify the following *residual-plot-options*:

NORMAL

produces a summary panel of the residual diagnostics, which consist of the following:

- histogram of residuals
- normal quantile plot of residuals

STD

produces a scatter plot of standardized residuals against time.

For more information about the precise meaning of the terms *maximal state shock statistics* and *prediction errors*, see the section “[Delete-One Cross Validation and Structural Breaks](#)” on page 773.

PRINTALL

turns on all the printing options for the procedure. All subsequent NOPRINT options in the procedure are ignored.

STATEINFO

prints two tables that provide information about the composition of the state vector in terms of the components specified in the model. One table describes the composition of state α_t , and the other table describes the diffuse vector δ and the regressors, which are part of the initial condition specification α_1 . For more information about the state space model notation, see the section “[State Space Model and Notation](#)” on page 760.

ZSPARSE

enables the exploitation of the sparsity of the Z_t matrices in the observation equation during the modeling calculations (see the section “[State Space Model and Notation](#)” on page 760 for further information). The use of this option can improve the computational efficiency of models that have a large state dimension and sparse Z_t matrices—that is, many of their elements are zero. You should use the ZSPARSE option only when the state dimension is sufficiently large (at least 30) and a good percentage (at least 50%) of Z_t entries are zero; otherwise, the computational efficiency can in fact degrade. For example, the illustration that is discussed in the section “[Getting Started: CSSM Procedure](#)” on page 722 is a good candidate for the use of the ZSPARSE option:

```
proc cssm data=mylib.Cigar plots=residual zsparse;
```

BY Statement

BY *variables* ;

A BY statement can be used in the CSSM procedure to process a data set in groups of observations that are defined by the BY variables. The model specified by using the MODEL and other statements is applied to all the groups defined by the BY variables. The BY variables are one or more variables in the input data set. The BY variables cannot be used in the model specification; in particular, they cannot be used as response variables or regressors in a MODEL statement.

COMPONENT Statement

COMPONENT *name* = (*var1 var2 ...* | *number1 number2 ...*) * *state* </options> ;

COMPONENT *name* = *state*[*integer*] </options> ;

COMPONENT *name* = (*Variable* | *Number*) * *state*[*integer*] </options> ;

The COMPONENT statement specifies a component (a linear combination of state elements), named *name*. You can use *name* later as a term in the right-hand side of the MODEL statement, which defines the observation equation. The estimate of *name* is output to the OUT= data set that is specified in the OUTPUT statement. In addition, you can print the component estimate by using the PRINT= option.

The first form of the COMPONENT statement defines a component as a dot product of a state subsection *state* and a row vector (*var1 var2 ...*). The value of *state* can be the name of a state subsection that is defined by using a STATE statement elsewhere in the program, or it can be the name of the state that is associated with a trend component defined by using a TREND statement elsewhere in the program (see the section “TREND Statement” on page 755 for more information about the naming of the state that is associated with a trend component). The row vector (*var1 var2 ...*), which can be either a list of numbers or a list of variables, must be of the same dimension as the actual dimension of the state subsection. The dot product form—also called the explicit dot product form—of the component specification is unambiguous; however, it requires detailed knowledge of the state vector underlying the *state* specification. Suppose that *mystate* is a two-dimensional state defined by a STATE statement elsewhere in the program and that X1 and X2 are (numeric) predictor variables. The following are valid examples of the dot product form of the COMPONENT statement:

```
component c1 = (x1 x2) * mystate;
component c2 = (1 1) * mystate;
```

The second and the third forms of the COMPONENT statement are a shortened version of the first form. The second form defines the component as a particular element of *state*—for example, *state*[3] defines the component as the third element of *state*. The specified *integer* must lie between 1 and *dim*, the nominal dimension of *state*. The second form of component specification has another important use when the STATE statement that defines *state* uses the TYPE= option to set its type or when *state* is associated with a trend component. In these cases, the second form of the component specification assumes additional meaning when the nominal state dimension and the actual state dimensions differ (specifically the state types LL, SEASON, CYCLE, and VARMA and the states associated with all the trend types). For example, if *state* is a three-dimensional seasonal component, *state*[2] signifies an appropriate linear combination of *state* that results in the second of the three seasonals that constitute the three-dimensional seasonal. Similar interpretation holds for the CYCLE type. For more information, see the sections “Multivariate Season” on

page 783 and “[Predefined Structural Models](#)” on page 779. The third form extends the second form by permitting multiplication by a variable or a number.

NOTE: A component that is based on a state associated with a trend component cannot be used as a right-hand side term in any MODEL statement. That is, it is defined purely for output purposes (either printed or output to a data set). However, it can be used as a term in the expression that is specified in an [EVAL](#) statement to build more complex linear combinations for output.

You can specify the following *options* to print the filtered or smoothed estimate of the component:

PRINT=FILTER | SMOOTH

PRINT=(*< FILTER >* *< SMOOTH >*)

requests printing of the filtered or smoothed estimate of the specified component.

DEPLAG Statement

DEPLAG *name*(*response-variable*) *lag-term1* *< lag-term2 ... >* ;

The DEPLAG statement defines a term, named *name*, that consists of a linear combination of lagged response variables. You can use *name* later as a right-hand-side term in the MODEL statement for the response variable, as specified in *name*(*response-variable*). For a multivariate model, a separate DEPLAG statement is needed for each MODEL statement that has a right-hand-side term that involves lagged response variables. The linear combination of lagged response variables is specified by using one or more *lag-terms*. Each *lag-term* specifies the lags that are associated with one of the response variables.

A *lag-term* is specified in one of the following forms:

lag-response-variable(**LAGS**=*maximum-lag*)

lag-response-variable(**LAGS**=(*integer1 integer2 ...*))

lag-response-variable(**LAGS**=*maximum-lag* **COEFF**=(*number1 number2 ...*) | (*variable1 variable2 ...*))

lag-response-variable(**LAGS**=(*integer1 integer2 ...*) **COEFF**=(*number1 number2 ...*) | (*variable1 variable2 ...*))

The *lag-response-variable* in the lag term specification can be the same as the response variable that corresponds to the model equation (which is specified in *name*(*response-variable*)), or it can be a different response variable.

The first form of specification is useful when all lags up to the *maximum-lag*, which must be a positive integer, are present in the lag term. The second form is useful when only certain lags, which are specified as a list of positive integers in parentheses, are present. In these two cases, the lag coefficients are not specified and they are treated as unknown parameters to be estimated from the data.

The **COEFF**= option in the last two forms enable you to specify lag coefficients. The **COEFF**= option must follow the **LAGS**= option. You can use the **COEFF**=(*number1 number2 ...*) option to specify the lag coefficients as known values. Similarly, you can use the **COEFF**=(*variable1 variable2 ...*) option to specify user-defined variables as lag coefficients; the user-defined variables can be functions of parameters (which are defined by using the PARMS statement) and input variables. However, the lag coefficients cannot depend on any of the response variables. The number of coefficients specified in the **COEFF**= option must exactly equal the number of lags specified in the **LAGS**= option.

There can be at most one DEPLAG statement associated with a particular MODEL statement (you can specify all the needed lag terms in a single DEPLAG statement).

As an illustration, let lagsFORy1 and lagsFORy2 represent the following linear combinations of lagged response variables Y1, Y2, and Y3:

$$\text{lagsFORy1} = \theta_{11}Y_{1t-1} + \theta_{12}Y_{1t-2} + \theta_{22}Y_{2t-2} + \theta_{23}Y_{2t-3} + 1.2Y_{3t-1} - 2.1Y_{3t-2}$$

$$\text{lagsFORy2} = \text{Phi1}Y_{1t-1} + \text{Phi2}Y_{1t-2} + \theta_{21}Y_{2t-1}$$

where Phi1 and Phi2 denote user-defined variables and θ_{ij} denote generic parameters. You can specify lagsFORy1 (which is used in the model equation for Y1) and lagsFORy2 (which is used in the model equation for Y2) as follows:

```
deplag lagsFORy1(y1) y1(lags=2) y2(lags=(2 3)) y3(lags=2 coeff=(1.2 -2.1));
deplag lagsFORy2(y2) y1(lags=2 coeff=(phi1 phi2)) y2(lags=1);
... more statements ...;
model y1 = lagsFORy1 ...;
model y2 = lagsFORy2 ...;
model y3 = ...;
... more statements ...;
```

assuming that the right-hand side of the MODEL equation for Y3 does not have a term that involves lags of response variables.

The DEPLAG statement in PROC CSSM has the same purpose as the DEPLAG statement in PROC UCM (see Chapter 30, “[UCM Procedure](#)”). However, there are many differences in the syntax of the two statements, mainly because PROC CSSM supports much more complex models. The syntax difference between the two DEPLAG statements can be illustrated by considering the differencing specification— $(1 - B)(1 - B^{12}) = (1 - B - B^{12} + B^{13})$ —in the well-known airline model (ARIMA(0, 1, 1)(0, 1, 1)₁₂ model). You can specify the lag-term that is implied by the differencing in the airline model in PROC UCM as follows:

```
deplag lags=(1)(12) phi=1 1 noest;
```

In PROC CSSM the same specification has the following form:

```
deplag airLags(y) y(lags=(1 12 13) coeff=(1 1 -1));
```

Both these specifications define the same lag-term: $(y_{t-1} + y_{t-12} - y_{t-13})$.

For an example of the use of lagged response variables in a model specification, see “[Example 14.13: Bivariate Model for Sales of Mink and Muskrat Furs](#)” on page 871. For more information about models that have dependent lags, see the section “[Models with Dependent Lags](#)” on page 785.

NOTE: Models that have lagged response variables are permitted only if the data form a time series (either univariate or multivariate). The CSSM procedure adds one more restriction on the models that use lagged response variables: the variables in the list that define a component in any of the COMPONENT statements must be free of unknown parameters. This restriction is artificial and is made primarily to reduce the overall complexity of the model. In future versions of the CSSM procedure, this restriction might go away.

DISPLAY Statement

DISPLAY < *table-list* > < / *options* > ;

The DISPLAY statement enables you to specify a list of display tables to display or exclude. This statement is similar to the ODS SELECT, ODS EXCLUDE, and ODS TRACE statements. However, the DISPLAY statement can improve performance when a large number of tables could be generated (such as in BY-group processing). The procedure processes the DISPLAY statement on a CAS server and thus sends only a subset of ODS tables to the SAS client. Because ODS statements are processed on a SAS client, first all the generated display tables are sent to the client, and then the client creates a subset.

If you use both DISPLAY and ODS statements together, the DISPLAY statement takes precedence over the ODS statements. Note that the ODS EXCLUDE statement processes tables that are sent to the client after they have been filtered by the DISPLAY statement. In some cases, it might appear that the ODS EXCLUDE statement is taking precedence because it can further filter the tables. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

You can specify the *table-list* as a list of table names, paths, partial pathnames, and regular expressions.

The table names that you can specify are listed in the section “[Displayed Output](#)” on page 799. A path is a table name that is prefixed with dot-separated grouping information. For example, a SelectionSummary table that a procedure produces during a selection routine might have the path *Bygroup1.Summary.SelectionSummary*. A partial pathname does not include all groups; for example, *SelectionSummary* and *Summary.SelectionSummary* are partial pathnames for *Bygroup1.Summary.SelectionSummary*.

When you specify a table name or partial pathname, all display tables whose paths end in the specified name are selected for display or exclusion. For example, both *SelectionSummary* and *Summary.SelectionSummary* select *Bygroup1.Summary.SelectionSummary*.

A regular expression is enclosed in forward slashes (/). For example, specifying “/tions/” selects all pathnames that contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is selected. Specifying “!/tions/” selects all pathnames that do not contain the substring “tions”; in particular, the *Bygroup1.Summary.SelectionSummary* table is not selected.

You can specify the following *options* after a slash (/):

CASESENSITIVE

performs a case-sensitive comparison of table names in the *table-list* to display table names when tables are subsetting for display. To preserve case, you must enclose table names in the *table-list* in quotation marks.

EXCLUDE

displays all display tables except those that you specify in the *table-list*.

EXCLUDEALL

suppresses display of all tables. This option takes precedence over the other options.

TRACE

displays the display table names, labels, and paths.

DISPLAYOUT Statement

DISPLAYOUT *table-spec-list* < / *options* > ;

The DISPLAYOUT statement enables you to create output tables from your displayed output. This statement is similar to the ODS OUTPUT statement. For more information about ODS, see *SAS Output Delivery System: Procedures Guide*.

The *table-spec-list* specifies a list of output tables to create. Each entry in the list has either a *key=value* format or a *key* format:

key=value specifies *key* as the ODS table name, path, or partial pathname, and specifies *value* as the output table name.

key specifies *key* as the ODS table name and also as the output table name.

The ODS table names that you can specify are listed in the section “[Displayed Output](#)” on page 799. You cannot specify the ODS table named OutputCasTables in the *table-spec-list*.

Table names and partial pathnames are discussed under the [DISPLAY](#) statement. The DISPLAYOUT statement does not support regular expressions.

You can specify the following *options* after a slash (/):

INCLUDEALL

creates output tables for all display tables. The name of the created output table is the same as the name of the corresponding display table. If you specify this option, the *table-spec-list* specification is ignored.

NOREPLACE

does not replace any existing output table of the same name.

REPEATED

replicates all output tables on all nodes.

EVAL Statement

EVAL *name* = *number1*variable1 + number2*variable2 + ...* </options> ;

The EVAL statement defines a linear combination, named *name*, of the terms used in the right-hand side of a MODEL statement. You can specify any variables (for example, predictor variables and names of components) in the expression of the EVAL statement; however, you cannot specify in this expression any observation disturbances that are specified by the IRREGULAR statement and any model terms that are specified by the DEPLAG statement. Suppose C1 and C2 are two components (defined by COMPONENT statements elsewhere in the program), T1 is a trend component, and X1 is a regression variable used in a model. The following are valid examples of the EVAL statement:

```
eval e1 = c1 - c2;
eval e2 = t1 + c1 + x1;
eval e2 = t1 + 2*c1 - 1.5*x1;
```

The estimates of linear combinations defined by the EVAL statement (for example, E1, E2, and E3) are output to the OUT= data set that is specified in the OUTPUT statement.

The components used in a given EVAL expression must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of linear combinations that can be specified; if two components in the right hand side of an EVAL expression share the same state subsection, a new component that combines the effect of these two components can always be defined.

In addition, you can print these estimates by using the following PRINT= options:

PRINT=FILTER | SMOOTH

PRINT=(< FILTER > < SMOOTH >)

requests printing of the filtered or smoothed estimate of the specified linear combination.

NOTE: The expression builder in the EVAL statement is primitive. For example, you cannot use parentheses to group terms.

ID Statement

ID *variable* <option> ;

The ID statement names a numeric variable to associate a sequence value—usually related to a timestamp—with the observations in the input data set. The ID statement is required. Internally, the CSSM procedure sorts the observations in ascending order by the ID variable within a BY group. If you also supply an **OBSINDEX** variable, the observations are sorted by both the ID variable and the OBSINDEX variable. Often the ID variable's values are SAS date, time, or datetime values, and each observation within a BY group has a unique ID value. Generally, however, the ID variable can be any numeric variable, and there can be multiple observations with the same ID value. If the ID values are SAS date, time, or datetime values, you can specify the associated unit of time—for example, day, week or month—by using the INTERVAL= option. A variable, **_ID_DELTA_**, is automatically created that can be used as any input data set variable in the programming statements. **_ID_DELTA_** contains the distance between two successive ID values. The first **_ID_DELTA_** value is arbitrarily taken as 1. If the INTERVAL= option is specified, the distance between the ID values is

measured in terms of the number of intervals; therefore, for regularly spaced data, `_ID_DELTA_` is identically equal to 1. You can specify the following *option* in the ID statement:

INTERVAL=*value*

specifies the unit of time interval that is used to measure the ID values. `INTERVAL=`*value* is used in conjunction with the ID variable to verify that the input data are in the proper order. For a complete discussion of the supported intervals, see Chapter 4, “Date Intervals, Formats, and Functions” ([SAS/ETS User’s Guide](#)).

IRREGULAR Statement

IRREGULAR *name* < *options* > ;

The IRREGULAR statement specifies a one-dimensional white noise component, which can be used to specify the observation error in a MODEL statement. You can specify the following *options* in the IRREGULAR statement:

PRINT=SMOOTH

requests printing of the smoothed estimate of the specified irregular component.

VARIANCE=*variable* | *number*

specifies the variance of the white noise. Any nonnegative value, including 0, is permissible. If the *variable* contains unknown parameters, they are estimated from the data. Similarly, if the `VARIANCE=` option is not specified, the variance is estimated from the data.

MODEL Statement

MODEL *response* = *variables* < / *options* > ;

A MODEL statement specifies an observation equation that describes a response variable as a sum of regression effects and components that are defined in the program. The response variable must be a numeric variable from the input data set. The variables used in the right-hand side of the model expression can be numeric variables from the input data set, numeric variables defined by using programming statements, or names of components that are specified in the COMPONENT, DEPLAG, TREND, or IRREGULAR statements.

For a multivariate model, a separate MODEL statement is needed for each of the response variables. In this case, the observation errors, which are specified in an IRREGULAR statement, must be different in each MODEL statement.

The components that are specified in a given MODEL statement must correspond to distinct state subsections. This requirement is imposed only to simplify the overall readability of the program and does not limit the type of models that can be specified; if two components on the right-hand side of a MODEL statement share the same state subsection, a new component that combines the effect of these two components can always be defined.

You can specify the following *options* in the MODEL statement; they must be separated from the list of terms in the right-hand side of the model equation by a slash (/):

AGGREGATE(START=*startFlag*)**SUM(START=*startFlag*)**

produces a table of full-sample predictions of the temporally aggregated values of the response variable that is specified in the MODEL statement. The variable that you specify in the START= option, *startFlag*, must be a zero-one variable that flags the start of an aggregation interval—equal to 1 at the start of an interval and 0 otherwise. For example, you can use this option to obtain the forecasts of weekly (or monthly) totals from a daily series. In this case, the value of *startFlag* is 1 at the start of the week (or month) and 0 otherwise. For more information, see the section “[Temporal Aggregation and Temporal Distribution](#)” on page 790. This option is valid only if the data form a time series (either univariate or multivariate). If you use the AGGREGATE option in a MODEL statement, you cannot use the DISTRIBUTE option in the same statement or in another MODEL statement.

DISTRIBUTE(START=*startFlag*)

indicates that the response variable that is specified in the MODEL statement is a temporally aggregated version of an unobserved variable. The variable that you specify in the START= option, *startFlag*, must be a zero-one variable that flags the start of an aggregation interval—equal to 1 at the start of an interval and 0 otherwise. This option can be used only when the data form a time series (either univariate or multivariate) and when the overall model specification does not contain terms that involve lagged response variables (that is, the model specification does not involve the use of [DEPLAG](#) statements). If you use the DISTRIBUTE option in a MODEL statement, you cannot use the AGGREGATE option in the same statement or in another MODEL statement. For more information, see the section “[Temporal Aggregation and Temporal Distribution](#)” on page 790.

PRINT=FILTER | SMOOTH**PRINT=(< FILTER > < SMOOTH >)**

requests printing of the filtered or smoothed estimate of the specified response variable. The filtered estimate is produced during the filtering phase, and the smoothed estimate is produced by the smoothing phase of the Kalman filter and smoother algorithm. The filtered estimate is also called the one-step-ahead forecast of the response variable. The smoothed estimate corresponds to the full-sample prediction of the response variable. Because the full-sample prediction of a nonmissing response value is that value itself, full-sample predictions are printed only for the missing response values.

OBSINDEX Statement

OBSINDEX *variable* ;

The OBSINDEX statement specifies a numeric input data variable that, together with the ID variable, uniquely identifies the observations within a BY group. This statement is essential for the reproducibility of the computations in situations where there can be multiple observations in a given BY group that have the same ID value. These types of situations arise when you are analyzing panels of time series or when the data are longitudinal. For examples of using this statement, see the section “[Getting Started: CSSM Procedure](#)” on page 722, “[Example 14.7: A Dynamic Factor Model for the Yield Curve](#)” on page 831, “[Example 14.9: Variable Bandwidth Smoothing for Longitudinal Data](#)” on page 848, and “[Example 14.11: Dynamic Panel Model for the Cigar Data](#)” on page 859.

OUTPUT Statement

OUTPUT *<options>* ;

The OUTPUT statement creates an optional output data set and also provides options to control certain aspects of the procedure output. If the OUT= option is specified, then an output data set is created to store estimates of the model components and series forecasts. If the OUT= option is omitted, then no data set is created by the OUTPUT statement. Other options in the OUTPUT statement produce additional information in the printed output generated by the procedure. For example, the AO and BREAK options control the search for additive outliers and structural breaks in the data, respectively.

AO(*< ALPHA=number > < MAXNUM=number > < MAXPCT=number >*)

controls the additive outlier search (see the section “[Delete-One Cross Validation and the Additive Outlier Detection](#)” on page 773 for more information). The ALPHA= suboption specifies the significance level for reporting the outliers. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of outliers to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option you can limit the number of outliers to search for according to a percentage of the series length. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.

ALPHA=number

specifies the significance level of the forecast confidence intervals. For example, ALPHA=0.05, which is the default, results in a 95% confidence interval.

BREAK(*< ALPHA=number > < MAXNUM=number > < MAXPCT=number >*)

controls the structural break search (for more information, see the section “[Structural Breaks in the State Evolution](#)” on page 774). In order for this option to have any effect, the CHECKBREAK option in one of the STATE or TREND statements, or the MAXSHOCK option in the OUTPUT statement, must be turned on. The ALPHA= suboption specifies the significance level for reporting the breaks. The default is ALPHA=0.05. The MAXNUM= suboption limits the number of breaks to search. The default is MAXNUM=5. The MAXPCT= suboption is similar to the MAXNUM= suboption. In the MAXPCT= option, you can limit the number of breaks to search for according to a percentage of the number of distinct time points in the data. The default is MAXPCT=1. When you specify both of these options, the lesser of the two search numbers is used.

MAXSHOCK

causes the computation of the maximal state shock chi-square statistic at each distinct time point in the input data set. These statistics are output to the data set that is specified in the OUT= option. A time series plot of these statistics is produced if the PLOTS=MAXSHOCK option is specified in the PROC CSSM statement. These statistics are useful for detecting structural breaks in the state evolution process. This option can be computationally expensive for a model with large state size. For more information, see the section “[Structural Breaks in the State Evolution](#)” on page 774.

OUT=libref.data-table

specifies an output data set for the forecasts. The output data set contains the ID variable, the OBSINDEX variable (if specified), the response variables, the one-step-ahead and out-of-sample response variable forecasts, the forecast confidence intervals, the smoothed values of the response series, and the one-step-ahead and smoothed estimates of the model components—including expressions that are defined by using the EVAL statement. For more information, see the section “[OUT= Data Set](#)” on page 802.

PDV

causes the inclusion of the variables (variables in the program data vector) that are defined by using the programming statements in the CSSM procedure in the OUT= data set. The parameters defined by the PARMs statement are also included. The output data set contains the values of these variables evaluated for all the rows in the input data set that is specified in the DATA= option. The parameters in the PARMs statement contain their estimated values.

PRESS

prints the prediction error sum of squares (PRESS) and the generalized cross validation error sum of squares (GCV). The PRESS table also reports the number of summands that are used in these sums of squares. For more information, see the section “[Delete-One Cross Validation and the Additive Outlier Detection](#)” on page 773.

PARMS Statement

PARMS *variable*< =*number*> *variable*< =*number*> < / *options* > ;

The PARMs statement declares the parameters of a model and optionally sets their initial values. You can also specify the lower and upper limits of their validity range. The parameters declared by using the PARMs statement are called *named parameters* throughout this chapter. A model can have additional parameters: any unspecified quantity in the model specification becomes part of the parameter vector. You can specify the following *options*:

LOWER=(*number1 number2 ...*)

LOWER=(*number*)

specifies the lower bounds for the specified parameters. The list can contain exactly one number, which is taken to be the lower bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no lower bound.

UPPER=(*number1 number2 ...*)

UPPER=(*number*)

specifies the upper bounds for the specified parameters. The list can contain exactly one number, which is taken to be the upper bound for all the listed parameters in the statement, or it must contain as many values as the number of parameters specified. A missing value, denoted by ., is a permissible value, which signifies that the parameter has no upper bound.

Programming Statements

To define the model, you can use most of the programming statements that are allowed in the SAS DATA step. For more information, see the *SAS DATA Step Statements: Reference*. For the most part, the syntax of programming statements used in PROC CSSM is identical to that used in the MODEL procedure (see Chapter 24, “MODEL Procedure” (*SAS/ETS User’s Guide*)) and the NLMIXED procedure (see Chapter 89, “The NLMIXED Procedure” (*SAS/STAT User’s Guide*)). However, there are some restrictions: the DATA step lagging and differencing functions are not allowed, and the use of character variables in the DATA step expressions is not permitted. These are not serious restrictions; usually you can overcome them by adding the variables that are created by such operations to the input data set before its use in the CSSM procedure.

SCORE Statement

SCORE <IN=score-table> <OUT=score-table> ;

The SCORE statement enables you to use the fitted model for scoring. By using the IN= and OUT= options in the SCORE statement, you can create, reuse, and update a score store. The score store contains sufficient context information so that you can perform many tasks, such as scenario analysis and forecasting for streaming data, without having to fit the model again. The score store is a binary large object (BLOB) table, which uses a binary file format that cannot be edited or viewed like a typical data table. For more information about using state space models for scoring, see the section “[Scoring with State Space Models](#)” on page 794.

IN=score-table

specifies a previously created score store to score the rows in the input data table. The rows in the input data table must represent a continuation of the sequential observation process that was used to create the specified score store. In particular, for a given BY group, the smallest value of the ID variable in the current input data table must be the same as or larger than the largest value of the ID variable in the data table that you used to create the score store. When you specify the IN= option in the SCORE statement, the statements that are used for model specification (such as the MODEL, STATE, and TREND statements, and so on) are not needed; in addition to the PROC CSSM statement and the SCORE statement, only the [BY](#) and [OUTPUT](#) statements are used when needed.

OUT <(positive-integer)> =score-table

specifies an output score-store table for storing the context information. The score store contains all the information that is needed for resuming the forecasting process from the last observation of a given BY group. If the OUT(*k*)= form of the option is used (where *k* is some positive integer), the score store keeps additional historical information so that the forecasting begins *k* time instances before the last observation. If *k* is larger than the total number of time points in a BY group, it is appropriately reduced. You should use the OUT(*k*)= form only at the time of score-store creation. In subsequent calls, the value of *k* that you specify at creation time remains in effect and cannot be changed. That is, *k* in OUT(*k*) is ignored when you also specify the IN= option.

When you specify both the IN= and OUT= options, the table names that you specify must be distinct. You can use the IN= and OUT= options by themselves or together. These options are used as follows:

Only OUT= Used for initial score-store creation.

Only IN= Used for scoring the rows of the input data table. This is useful for scenario analysis, where the scoring is done repeatedly, each time for different predictor settings. For an example of this use case, see “[Example 14.19: Scenario Analysis Using Scoring](#)” on page 894.

Both IN= and OUT= Used for creating an updated score store that incorporates new information. This is used in the streaming data setting, where new sets of observations become available on a regular basis and the score store must be updated to take into account the latest information. For an example of this use case, see “[Example 14.20: Monitoring Streaming Data Using Scoring](#)” on page 897.

NOTE: Scoring is not currently supported in situations where temporal aggregation or temporal distribution is requested. For more information, see the AGGREGATE and DISTRIBUTE options in the **MODEL** statement.

SIMSMOOTH Statement

SIMSMOOTH < **INMODEL**=*blob-table* > < **OUTMODEL**=*blob-table* > < *options* > ;

The SIMSMOOTH statement enables you to use the fitted model for simulation smoothing. (For more information, see the section “[Simulation Smoothing](#)” on page 787.) The **OUTMODEL=** option enables you to store the fitted model in a binary large object (BLOB) table to use later for simulation smoothing. The **INMODEL=** option enables you to load a previously stored fitted model and use it for simulation smoothing. The other options in this statement enable you to control different parts of the simulation smoothing process. For an illustration of simulation smoothing, see “[Example 14.21: Simulation-Smoothing-Based Sampling Distribution of the Sum of Forecasts](#)” on page 901.

You can specify the following *options*:

INMODEL=*blob-table*

specifies a previously created BLOB table that contains the fitted model for the input data table. When you specify this option in the SIMSMOOTH statement, the statements that are used for model specification (such as the MODEL, STATE, and TREND statements) are not needed. In addition to the PROC CSSM and SIMSMOOTH statements, only the options that control the simulation smoothing steps, such as the **NSIM=**, **SEED=**, and **OUTPRED=** options, are used.

NSIM=*number*

specifies the number of simulations to generate, where *number* is a positive integer. By default, NSIM=1.

OUTCOMP=*libref.data-table*

specifies an output data table to store the simulated components. This table contains the ID statement variable, the OBSINDEX statement variable (if specified), and the simulated components. For more information, see the section “[Output Tables Associated with Simulation Smoothing](#)” on page 788.

OUTMODEL=*blob-table*

specifies a BLOB table to store the fitted model specification for later use in simulation smoothing. When you specify this option in the SIMSMOOTH statement, other options in this statement (such as the INMODEL= or NSIM= option) are ignored.

OUTPRED=*libref.data-table*

specifies an output data table to store the simulated predictions of the missing response values. This table contains the ID statement variable, the OBSINDEX statement variable (if specified), and the simulated predictions of the missing response values. For more information, see the section “[Output Tables Associated with Simulation Smoothing](#)” on page 788.

OUTSTATE=*libref.data-table*

specifies an output data table to store the simulated latent states. This table contains the ID statement variable, the OBSINDEX statement variable (if specified), and the simulated states. For more information, see the section “[Output Tables Associated with Simulation Smoothing](#)” on page 788.

SEED=*seed*

specifies the start of the set of random number seeds to use during the simulation process. As an example, if the number of simulations that you specify in the NSIM= option is 100 and SEED=5, then the seeds between 5 and 104 are sequentially used for random number generation during the 100 simulations. By default, SEED=1.

The SIMSMOOTH statement is used both in creating the fitted-model-specification BLOB table (using the OUTMODEL= option) and later in simulation smoothing (using the INMODEL= option).

NOTE: Simulation smoothing is not currently supported in situations where temporal aggregation or temporal distribution is requested. For more information, see the AGGREGATE and DISTRIBUTE options in the MODEL statement.

STATE Statement

STATE *name (dim)< options>* ;

The STATE statement specifies a subsection of α_t , the overall state vector at time t (for more information, see the section “[State Space Model and Notation](#)” on page 760). Consider the state equations that define the state space model:

$$\begin{aligned}\alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + \mathbf{c}_{t+1} + \eta_{t+1} \\ \alpha_1 &= \mathbf{c}_1 + \mathbf{A}_1 \delta + \mathbf{W}_1 \gamma + \eta_1\end{aligned}$$

You can specify multiple STATE statements, each specifying a separate subsection. It is assumed that the subsections that are specified by using different STATE statements are mutually independent. This independence assumption implies a block-diagonal structure for the transition matrices $\mathbf{T}_t$ and the disturbance covariances $\mathbf{Q}_t$ for all $t \geq 1$. An appropriate block structure also applies to $\mathbf{W}_t$ and $\mathbf{A}_1$. The *options* in the STATE statement provide complete control over the description of the relevant blocks of $\mathbf{T}_t$, $\mathbf{Q}_t$, $\mathbf{W}_t$, and $\mathbf{A}_1$. The argument *dim* (a positive integer in *name (dim)*) specifies the nominal dimension of this subsection. In most situations, the nominal dimension and the actual dimension of the state subsection are the same. However, when you specify the TYPE= option, the actual dimension of the state subsection can be different

from the nominal dimension. The **TYPE=** option simplifies the state specification task for some commonly needed models.

NOTE: The **T**, **COV**, **W**, and **COV1** options, described later in this section, specify the relevant blocks of T_t , Q_t , W_t , and Q_1 , respectively. The structure of these matrix blocks is described in a similar way in the option descriptions. For example, the specification **COV(I)** corresponds to the identity form, **COV(D)** corresponds to the diagonal form, and **COV(G)** corresponds to the general form of the Q_t block.

You can use the following *options* in the STATE statement to specify the system matrices T_t , Q_t , W_t , and A_1 and to request printing of their estimates when they contain unknown parameters. You can also request the checking of unexpected changes—structural breaks—in the evolution of this state subsection by using the **CHECKBREAK** option.

A1(nd)

treats the last nd elements of the state subsection as diffuse. This becomes the dimension of the relevant subsection of the diffuse vector δ . The A_1 block is created by using appropriate columns of the identity matrix. The value of nd must lie between 1 and the nominal dimension, dim . The absence of this option signifies that this subsection of α_t is nondiffuse. If both the **COV1** and **A1** options are specified, the last nd rows and columns of the matrix specified in the **COV1** option are taken to be 0. This option cannot be used together with the **RANK=** option of the **COV1** option.

CHECKBREAK< (ELEMENTWISE | OVERALL) >

turns on the checking of breaks for this state subsection. The **ELEMENTWISE** suboption requests the elementwise checking of any unexpected change in the state subsection as it evolves from one time point to the next. The **OVERALL** suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The **ELEMENTWISE** suboption is the default. Unless the **PRINT=BREAKDETAIL** option is specified, only a summary of the most significant breaks is produced. If the **PRINT=BREAKDETAIL** is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the **ELEMENTWISE** suboption and one for the **OVERALL** suboption. For more information about the structural break detection process, see the section “[Structural Breaks in the State Evolution](#)” on page 774. For an example of the use of the **CHECKBREAK** option, see “[Example 14.8: Diagnostic Plots and Structural Break Analysis](#)” on page 841.

COV(D) <= (var1 var2 ...) | (number1 number2 ...) >

COV(G) <= (var1 var2 ...) | (number1 number2 ...) >

COV(I) <= (variable) | (number) >

COV(RANK=integer)

specifies the relevant block of the disturbance covariance Q_t (for $t \geq 2$) in the transition equation. As with the **T** option, the absence of this option signifies that this Q -block consists of only zeros. The structure of the Q -block is also similarly specified. However, the following differences exist:

- The list that is specified to form the covariance must result in a symmetric, positive semidefinite matrix. For an example, see “[Example 14.5: A User-Defined Trend Model](#)” on page 823.
- You can specify a rank constraint on the Q -block by specifying **COV(RANK=integer)**, where the specified integer must lie between 1 and dim . A rank constraint is permissible only for the general form and only when its elements are not specified by using a list.
- The convention of treating unset variables as structural zeros, which is used in specifying sparsity of the T -block, is not used in the Q -block specification. Whenever you explicitly specify the

entries of the Q-block by specifying a list of variables in parentheses, all variables in the list must evaluate to nonmissing values.

The following examples illustrate different ways of specifying a Q-block. It is assumed that $dim = 2$.

- COV(G) specifies a general-form Q-block, which contributes $(2 * (2 + 1))/2 = 3$ unspecified elements to the parameter vector θ .
- COV(RANK=1) specifies a rank-one Q-block.

COV1(D) <= (var1 var2 ...) | (number1 number2 ...) >

COV1(G) <= (var1 var2 ...) | (number1 number2 ...) >

COV1(I) <= (variable) | (number) >

COV1(RANK=integer)

specifies the relevant block of the initial state covariance Q_1 . The different options in this case have the same meaning as the options of the **COV** option. However, the following differences exist:

- If the elements of Q_1 are specified by a list of variables in parentheses, then these variables must evaluate to constant values. In particular, they can depend on parameters that are specified by the **PARMS** statements; however, they cannot depend on any of the input data columns.
- If the initial condition is partially diffuse (that is, the diffuse dimension nd specified in the **A1** option is nonzero), the last nd rows and columns of the matrix specified in **COV1** are taken to be zero. Moreover, if the elements of Q_1 are specified by a list, its number of elements must correspond to a matrix of dimension $(dim - nd)$.

PRINT=AR | BREAKDETAIL | COV | COV1 | MA | T

PRINT=(<AR> <BREAKDETAIL> <COV> <COV1> <MA> <T>)

requests printing of the respective system matrices and the printing of the break statistics at each distinct time point. You can specify **PRINT=AR** or **PRINT=MA** only if you specify the **TYPE=VARMA** option. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed. For the **BREAKDETAIL** suboption to have any effect, the **CHECKBREAK** option must be turned on. If **TYPE=** option is used, the result of **PRINT=COV** can be different than the matrix supplied in the **COV=** option.

SINPUT = (var1 var2 ...) | (number1 number2 ...)

specifies the relevant dim -dimensional block of the state input vector c_t . The absence of this option signifies that this block of the c_t vector consists of only zeros. If the elements of c_t are specified by a list of variables in parentheses, then these variables must be independent of unknown parameters. In particular, they cannot be functions of parameters that are defined by the **PARMS** statements.

T(D) <= (var1 var2 ...) | (number1 number2 ...) >

T(G) <= (var1 var2 ...) | (number1 number2 ...) >

T(I) <= (variable) | (number) >

specifies the relevant block of the transition matrix T_t . The absence of this option signifies that this block consists of only zeros. You can specify the structure of the T-block by specifying **T(I)** for the identity form, **T(D)** for the diagonal form, and **T(G)** for a general unstructured form. In addition, you can explicitly specify the entries of the T-block by specifying a list of numbers in parentheses, or by specifying in parentheses a list of variables that are defined by using the programming statements. The

unspecified elements of the T-block are included in the list of parameters to be estimated from the data. If the elements of the T-block are supplied by a list in parentheses, the number of elements in the list depends on its structure. For the diagonal form, the list must contain exactly *dim* elements. In the case of the identity form—T(I)—the block is already fully specified; however, a specification T(I)=(*variable*) is understood to mean that the identity block is scaled by the specified *variable* (or a *number*). In the general case—T(G)—the list must consist of *dim* * *dim* elements, specified in a rowwise fashion. An inappropriate number of elements in the list results in a syntax error.

The following examples illustrate different ways of specifying the transition matrix. It is assumed that *dim* = 2.

- T(I) specifies that the T-block is a two-dimensional identity matrix.
- T(D) specifies that the T-block is a two-dimensional diagonal matrix. The two unspecified diagonal entries become part of the parameter vector θ .
- T(D)=(1.1 2) fully specifies the two-dimensional diagonal T-block.
- T(D)=($X_1 X_2$) specifies a two-dimensional diagonal T-block where the diagonal elements are dynamically calculated based on the values of the variables X_1 and X_2 . In this case the T-block can change with time if X_1 or X_2 changes with time.
- T(G) specifies a general form T-block (with $2^2 = 4$ unspecified elements).
- T(G)=($X_1 X_2 X_3 X_4$) specifies a general form T-block where the first row is formed by X_1 and X_2 , and the second row is formed by X_3 and X_4 .

In practice the transition matrix is often sparse—that is, many of its elements are 0. The algorithms in the CSSM procedure exploit this sparsity structure for computational efficiency. Whenever you explicitly specify the entries of the T-block by specifying a list of variables in parentheses, you can leave the variables that correspond to the zero elements *unset*. These unset variables are treated as structural zeros by the CSSM procedure. The section “[Sparse Transition Matrix Specification](#)” on page 765 further explains how to use this sparsity convention.

TYPE=WN

TYPE=RW

TYPE=LL <(SLOPECOV(I | D | G) <= (var1, var2, ...) | (number1, number2, ...) >)>

TYPE=LL (SLOPECOV(RANK=*integer*)

TYPE=SEASON (LENGTH=*integer* <DROPH=*number-list*> <KEEPPH=*number-list*>)

TYPE=CYCLE <(<CT> <RHO=*variable* | *number*> <PERIOD=*variable* | *number*>)>

TYPE=VARMA (<p <(I | D)> =*integer*> <q<(D)> =*integer*>)

specifies a state subsection that corresponds to the specified type. You can specify either a number or a variable for the RHO= and PERIOD= suboptions. When TYPE=VARMA, the autoregressive and moving average orders can be at most 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$). Moreover, by using the D and I flags with the order specification, you can impose additional structure on the autoregressive and moving average coefficient matrices—for example, specifying TYPE=VARMA(P=1) implies a VAR(1) model with general autoregressive coefficient matrix, whereas specifying TYPE=VARMA(P(D)=1) implies a VAR(1) model with diagonal autoregressive coefficient matrix. If you specify the TYPE= option, the T, COV1, SINPUT, and A1 options are not needed. In fact they are ignored, since the transition matrix T_t and the matrices in the initial condition (Q_1 and A_1) are implicitly defined by the choice of the type. However, the COV and W options can be useful. In fact, the specification of the

COV option does play a key role in the eventual form of $\mathbf{Q}_t$ —the covariance of the disturbance term in the transition equation. For the types LL, CYCLE, SEASON, and VARMA, the dimension of the resulting state subsection is a certain multiple of *dim*, the nominal dimension in the STATE statement. For example, the following specification results in a state subsection, named `cycleState`, of dimension $2*dim$:

```
state cycleState(dim) cov(g) type=cycle;
```

The name `cycleState` corresponds to the state underlying a *dim*-dimensional cycle component. All of these special state types require that the data be regular (replication is permissible); the only exception is **TYPE=Cycle(CT)**, which defines a continuous-time cycle and is applicable to any data type. [Table 14.2](#) summarizes some of this information for easy reference. For more information about these state types, see the section “[Predefined Structural Models](#)” on page 779.

The **TYPE=LL** specification results in a state that corresponds to a multivariate local linear trend. It is governed by two covariance matrices: the **COV** option specifies the covariance that corresponds to the level equation, and the **SLOPECOV** suboption specifies the covariance used in the slope equation. The omission of the **SLOPECOV** suboption signifies that the covariance used in the slope equation is zero. The form of the **SLOPECOV** suboption is exactly the same as that of the **COV** option.

The **TYPE=Cycle** option results in a state that corresponds to a (stochastic) cycle. By default, this cycle is assumed to be for the regular data type. If **TYPE=Cycle(CT)**, the resulting cycle is applicable to any data type. The CT option is available only for *dim* = 1; that is, only a univariate cycle is available for the irregular data type. The cycle specification depends on a covariance matrix and two numbers: the damping factor **RHO** and the cycle period **PERIOD**. The covariance can be specified by the **COV** option. The damping factor is specified by the **RHO=** suboption; its value must lie between 0.0 and 1.0. The cycle period can be specified by the **PERIOD=** suboption. If the CT suboption is not included, the period value must be larger than 2.0. On the other hand, if the CT suboption is included, its value must be strictly positive. If these parameters are not specified, they are estimated from the data.

The **TYPE=SEASON(LENGTH=integer)** specifies a multivariate trigonometric season that contains the full set of harmonics (for more information, see “[Multivariate Season](#)” on page 783). In some cases, you might want to drop some of the harmonics from this complete set to obtain a more parsimonious trigonometric season specification. You can use the **DROPH=** (to drop) or **KEEPH=** (to keep) suboption to control the harmonics that are included in the season specification as follows:

```
TYPE=SEASON(
  LENGTH=integer
  < DROPH=number-list | n TO m BY p>
  < KEEPH=number-list | n TO m BY p>
)
```

The **DROPH=** and **KEEPH=** lists can include any integer between 1 and *LENGTH*/2 if the season length is even and any integer between 1 and (*LENGTH* – 1)/2 if the season length is odd. For example, the following specification results in a specification of a trigonometric season with a season length 12 that consists of only the first four harmonics ζ_j , $j = 1, 2, 3, 4$:

```
type=season(length=12 DROPH=5 6) ...;
```

The last two *high*-frequency harmonics, ξ_5 and ξ_6 , are dropped. The DROPH= suboption cannot be used with the KEEPH= suboption.

Table 14.2 Summary of Predefined State Types

Type	Description	Parameters	State Dimension
WN	<i>dim</i> -variate white noise	COV	<i>dim</i>
RW	<i>dim</i> -variate random walk	COV	<i>dim</i>
LL	<i>dim</i> -variate local linear	COV, SLOPECOV	$2 * \textit{dim}$
SEASON(LENGTH= <i>length</i>)	<i>dim</i> -variate season	COV	$(\textit{length} - 1) * \textit{dim}$
CYCLE	<i>dim</i> -variate cycle	COV, RHO, PERIOD	$2 * \textit{dim}$
VARMA(P= <i>p</i> Q= <i>q</i>)	<i>dim</i> -variate VARMA(<i>p</i> , <i>q</i>)	COV, AR, MA	$\textit{dim} * \max(\textit{p}, \textit{q} + 1)$

W(D)= (*var1 var2 ...*) | (*number1 number2 ...*)

W(G)= (*var1 var2 ...*) | (*number1 number2 ...*)

W(I) <= (*variable*) | (*number*) >

specifies the relevant block of the design matrix $\mathbf{W}_t$ in the transition equation. The W-block is of dimension $sdim \times sg$, where *sdim* denotes the actual dimension of the state subsection (which can be the same as *dim*, the nominal dimension, or different if the TYPE= option is used) and *sg* denotes the desired size of the subsection of the overall state regression vector $\boldsymbol{\gamma}$. The absence of this option signifies that the state equation does not contain any regression effects. The number of variables supplied in the W(G)= list option must be a multiple of *sdim*. For example, if *sdim* = 4 and the W(G)= list contains 8 variables, then the implied size of $\boldsymbol{\gamma}$ subsection is 2. If the W(D)= or W(I)= option is used, then the W-block is assumed to be an *sdim*-dimensional diagonal matrix and the W(D)= list must contain exactly *sdim* variables. For examples of the use of this option, see “[Example 14.8: Diagnostic Plots and Structural Break Analysis](#)” on page 841, “[Example 14.10: A Transfer Function Model for the Gas Furnace Data](#)” on page 853, and “[Example 14.11: Dynamic Panel Model for the Cigar Data](#)” on page 859.

TREND Statement

TREND *name* (*type*)< *options* > ;

The TREND statement defines a term in the model that follows a stochastic pattern of a certain predefined type. The *options* in the TREND statement enable you to specify a wide variety of commonly used stochastic patterns. Each TREND statement in effect stands for a special pair of STATE and COMPONENT statements. You can specify more than one TREND statement. Each separate TREND statement defines a component that is assumed to be independent of all other component specifications in the model. Very often the TREND statement is used to specify a component that captures the time-varying level of the data. However, in many cases it is also used to define components of a more general nature; for example, it can be used to define a noise component that follows a stationary ARMA model.

You can refer to the state that is associated with a TREND statement by appending the string “_state_” to the end of its name. For example, *name_state_* is the state that is associated with a trend named *name*. You can use *name_state_* in a [COMPONENT](#) statement to define a linear combination of its elements. The estimate

of this linear combination can then be printed or output to a data set. The nominal dimension of `name_state_` is taken to be 1, or the number of variables in the list that is specified in the **CROSS=** option in the **TREND** statement that is used to define `name` (see “[Example 14.4: Smoothing of Repeated Measures for Longitudinal Data](#)” on page 814 for an example of such use of the **COMPONENT** statement).

Some of these trend specifications are applicable to all the data types—that is, they can be used for both regular data types and irregular data types, whereas the others require that the data be regular or regular with replication. Of course, the trend specification is only part of the overall model specification. Therefore, the other parts of the model can imply additional constraints on the data type.

[Table 14.3](#) lists the available trend models and their data requirements. The *type* column shows the admissible keywords that signify the particular trend type. For brevity, the Data Type column groups the data types regular and regular with replication into one category: regular. For more information about these trend models, see the section “[Predefined Trend Models](#)” on page 776.

Table 14.3 Summary of Trend Types

<i>type</i>	Data Type	Description	Parameters
ARIMA(<i>P=integer D=integer ...</i>)	Regular	ARIMA model specification	AR and MA coefficients, and the error variance σ^2
DLL	Regular	Damped local linear	Level and slope σ_1^2, σ_2^2 , damping factor ϕ
LL	Regular	Local linear	Level and slope σ_1^2, σ_2^2
RW	Regular	Random walk	Level σ^2
DECAY	Irregular	A type of decay pattern	Level σ^2 , decay rate ϕ
DECAY(OU)	Irregular	Ornstein-Uhlenbeck decay pattern	Level σ^2 , decay rate ϕ
GROWTH	Irregular	A type of growth pattern	Level σ^2 , growth rate ϕ
GROWTH(OU)	Irregular	Ornstein-Uhlenbeck growth pattern	Level σ^2 , growth rate ϕ
PS(<i>order</i>)	Irregular	Polynomial spline of a given order	Level σ^2

The keyword specification of different trend types, except possibly the ARIMA trend, is quite simple. For example, the following statement specifies `polySpline` as a trend of the type second-order polynomial spline:

```
trend polySpline(ps(2));
```

Similarly, the following statement defines `dampedTrend` as a damped local linear trend:

```
trend dampedTrend(dll) slopevar=x;
```

The variance parameter that governs the slope equation of this trend type is given by a variable `x`, which must be defined elsewhere in the program. The other parameters that define `dampedTrend` are left unspecified (and are estimated by using the data).

The ARIMA trend specification permits specification of trends that follow an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model. The specification of ARIMA models requires some notation, which is explained first.

Let B denote the backshift operator—that is, for any sequence ζ_t , $B\zeta_t = \zeta_{t-1}$. The higher powers of B represent larger shifts (for example, $B^3\zeta_t = \zeta_{t-3}$). A random sequence ζ_t follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with nonseasonal autoregressive order p , seasonal autoregressive order P , nonseasonal differencing order d , seasonal differencing order D , nonseasonal moving average order q , and seasonal moving average

order Q if it satisfies the following difference equation, which is specified in terms of the polynomials in the backshift operator, where a_t is a white noise sequence and s is the season length:

$$\phi(B)\Phi(B^s)(1-B)^d(1-B^s)^D\zeta_t = \theta(B)\Theta(B^s)a_t$$

The polynomials ϕ , Φ , θ , and Θ are of orders p , P , q , and Q , respectively, which can be any nonnegative integers. The season length s must be a positive integer. For example, ζ_t satisfies an ARIMA(1,0,1) model (that is, $p = 1$, $d = 0$, $q = 1$, $P = 0$, $D = 0$, and $Q = 0$) if

$$\zeta_t = \phi_1\zeta_{t-1} + a_t - \theta_1a_{t-1}$$

for some coefficients ϕ_1 and θ_1 and a white noise sequence a_t . Similarly, ζ_t satisfies an ARIMA(0,1,1)×(0,1,1)₁₂ model if

$$\zeta_t = \zeta_{t-1} + \zeta_{t-12} - \zeta_{t-13} + a_t - \theta_1a_{t-1} - \Theta_1a_{t-12} + \theta_1\Theta_1a_{t-13}$$

for some coefficients θ_1 and Θ_1 and a white noise sequence a_t . An ARIMA process is zero-mean, stationary, and invertible if $d = 0$, $D = 0$, and the defining polynomials ϕ , Φ , θ , and Θ have all their roots outside the unit circle—that is, their absolute values are strictly larger than 1.0. It is assumed that the coefficients of the polynomials ϕ , Φ , θ , and Θ are constrained so that the stationarity and invertibility conditions are satisfied. The unknown coefficients of these polynomials become part of the model parameter vector that is estimated by using the data. The general form of the ARIMA trend specification is as follows:

ARIMA(<P=integer> <D=integer> <Q=integer> <SP=integer> <SD=integer> <SQ=integer> <S=integer>)

By default, the different orders are equal to 0 and the season length is equal to 1. The following examples illustrate a few different ARIMA trend specifications. The following statement defines `ima` as an integrated moving average trend:

```
trend ima(arima(d=1 q=1));
```

The following statement defines `airTrend` as a trend that satisfies the well-known airline model (ARIMA(0,1,1)(0,1,1)₁₂ model) for monthly seasonal data:

```
trend airTrend(arima(d=1 q=1 sd=1 sq=1 s=12));
```

The following statement defines `arma11` as a zero-mean ARMA(1,1) trend with autoregressive parameter fixed to 0.1:

```
trend arma11(arima(p=1 q=1)) ar=0.1;
```

For an example of the use of the ARIMA trend specification, see “[Example 14.6: Model with Multiple ARIMA Components](#)” on page 827.

You can use the following *options* in the TREND statement to specify the trend parameters and to request printing of the trend estimates. In addition, you can create a custom combination of a given trend type by specifying the **CROSS=** option to create a more general trend. For an example of using the **CROSS=** option, see the section “[Getting Started: CSSM Procedure](#)” on page 722 and the discussion of the second model in “[Example 14.4: Smoothing of Repeated Measures for Longitudinal Data](#)” on page 814. You can also check for the unexpected changes in the trend component by using the **CHECKBREAK** option.

AR= $\phi_1 \phi_2 \dots \phi_p$

lists the values of the coefficients of the nonseasonal autoregressive polynomial

$$\phi(B) = 1 - \phi_1 B - \dots - \phi_p B^p$$

where the order p is specified in the ARIMA trend specification. The coefficients ϕ_i must define a stationary autoregressive polynomial.

CHECKBREAK<(**ELEMENTWISE** | **OVERALL**)>

turns on the checking of breaks for this trend component. The **ELEMENTWISE** suboption requests the elementwise checking of any unexpected change in the state subsection that is associated with the trend component. The **OVERALL** suboption requests a similar check for the entire state subsection—that is, in this case the change is measured as a multidimensional change. The **ELEMENTWISE** suboption is the default. Unless the **PRINT=BREAKDETAIL** option is specified, only a summary of the most significant breaks is produced. If the **PRINT=BREAKDETAIL** is specified, tables that contain the break significance statistics at every distinct time point are produced—one for the **ELEMENTWISE** suboption and one for the **OVERALL** suboption. If the **CROSS=** option is specified and the **CROSS=** list contains more than one variable, the **OVERALL** suboption considers subsections that are associated with each **CROSS=** variable separately. For more information about the structural break detection process, see the section “[Structural Breaks in the State Evolution](#)” on page 774.

CROSS=(*var1*, *var2*, ...)

CROSS(MATCHPARM)=(*var1*, *var2*, ...)

creates a linear combination of one or more independent trend components that is based on the variables in the list. If the parameters of the trend are specified by options such as the **LEVELVAR=** option or the **PHI=** option, these parameters are shared by these constituent trends. For example, suppose that the **CROSS=** list contains two variables (X_1 and X_2) and the trend specification is of the type **RW**. The effect of **CROSS**=(X_1, X_2) is to create a component $\mu_t = X_1\mu_{1,t} + X_2\mu_{2,t}$, where $\mu_{1,t}$ and $\mu_{2,t}$ are two independent random walk trends. Moreover, if the random walk trend specification uses the **LEVELVAR=** option to specify the variance parameter, $\mu_{1,t}$ and $\mu_{2,t}$ share the same variance parameter; otherwise, two separate variance parameters are assigned to these random walks. If the second form of the **CROSS** option, **CROSS(MATCHPARM)=**, is used, then the constituent trends share all the relevant parameters no matter how they are specified. The **CROSS=** option is useful for a variety of situations. For example, suppose X is an indicator variable that is 1 before a certain time point t_0 and 0 thereafter. Then **CROSS**=(X) has the effect of turning off the trend component after time t_0 . Similarly, suppose G_1 and G_2 are indicators for gender—for example, $G_1 = (\text{GENDER}=1)$ and $G_2 = (\text{GENDER}=0)$ for male and female cases, respectively. Then **CROSS**=(G_1, G_2) results in separate trends according to the gender. The variables in the **CROSS=** list must be free of unknown parameters.

The **CROSS=** option can be computationally expensive; computationally it is equivalent to specifying as many separate trends as the number of variables in the specified list.

LEVELVAR=*variable* | *number*

specifies the disturbance variance parameter for all the trend types. For trend types **LL** and **DLL**, this option specifies σ_1^2 . Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the **LEVELVAR=** option is not specified, σ^2 is estimated from the data.

MA= $\theta_1 \theta_2 \dots \theta_q$

lists the values of the coefficients of the nonseasonal moving average polynomial,

$$\theta(B) = 1 - \theta_1 B - \dots - \theta_q B^q$$

where the order q is specified in the ARIMA trend specification. The coefficients θ_i must define an invertible moving average polynomial.

NODIFFUSE

treats the diffuse elements in the initial state of the state subsection underlying the trend component as nondiffuse. This option is applicable to all trend types except ARIMA. For the ARIMA trend type, this option is ignored even if the nonseasonal or seasonal differencing orders are nonzero. The diffuse elements are assumed to be independent, zero-mean, Gaussian variables. Their variances become part of the parameter vector and are estimated by using the data. This option is useful for creating a trend component that can be interpreted as a deviation from an overall trend component (with diffuse initialization), which is defined separately.

PHI=*variable* | *number*

specifies the value of ϕ for trend types DLL, DECAY, DECAY(OU), GROWTH, and GROWTH(OU). For the type DLL, the specified value must be between 0.0 and 1.0. For types DECAY and DECAY(OU), ϕ must be strictly negative. For types GROWTH and GROWTH(OU), ϕ must be strictly positive. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the PHI= option is not specified, ϕ is estimated from the data.

PRINT=**BREAKDETAIL** | **COV** | **COV1** | **FILTER** | **SMOOTH** | **T**

PRINT= (< **BREAKDETAIL** > < **COV** > < **COV1** > < **FILTER** > < **SMOOTH** > < **T** >)

requests printing of the respective system matrices of the state equation that underlies the specified trend, the printing of its filtered and smoothed estimates, and the printing of the break statistics at each distinct time point. For the BREAKDETAIL suboption to have any effect, the [CHECKBREAK](#) option must be turned on. If any of these matrices are time-varying, the matrix that corresponds to the first time instance is printed.

SAR= $\Phi_1 \Phi_2 \dots \Phi_P$

lists the values of the coefficients of the seasonal autoregressive polynomial

$$\Phi(B^s) = 1 - \Phi_1 B^s - \dots - \Phi_P B^{sP}$$

where the order P is specified by using the SP= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Φ_i must define a stationary autoregressive polynomial.

SMA= $\Theta_1 \Theta_2 \dots \Theta_Q$

lists the values of the coefficients of the seasonal moving average polynomial

$$\Theta(B^s) = 1 - \Theta_1 B^s - \dots - \Theta_Q B^{sQ}$$

where the order Q is specified by using the SQ= option in the ARIMA trend specification and the season length s is specified in the S= option. The coefficients Θ_i must define an invertible moving average polynomial.

SLOPEVAR=*variable* | *number*

specifies the second disturbance variance parameter, σ_2^2 , for trend types LL and DLL. Any nonnegative value, including 0, is permissible. If *variable* contains unknown parameters, they are estimated from the data. Similarly, if the SLOPEVAR= option is not specified, σ_2^2 is estimated from the data.

Details

Throughout this section, vectors and matrices are denoted by boldface letters. Generally, Greek letters (such as α , β , and ϵ) denote unobserved or latent quantities—often estimated from the data—that represent model parameters, latent states, or noise variables. Capital letters such as X , Y , and Z are used to denote the observed data variables. Whenever there is no ambiguity, it is assumed that the matrices have appropriate dimensions when they are being multiplied—in particular, the vectors behave as column vectors or row vectors as the need arises. On many occasions, matrices are described inline—that is, they are described as parenthesized lists, in a rowwise fashion, with the rows separated by a comma. The term “dot product” is used to describe the scalar that results from the product of a row vector with a (conforming) column vector.

State Space Model and Notation

The (linear) state space model is described in the literature in a few different ways and with varying degree of generality. The description given in this section loosely follows the description given in Durbin and Koopman (2012, chap. 6, sec. 4). This formulation of SSM is quite general; in particular, it includes nonstationary SSMs with time-varying system matrices and state equations with a diffuse initial condition (these terms are defined later in this subsection).

Suppose that observations are collected in a sequential fashion (indexed by a numeric variable τ) on some variables: the vector $\mathbf{y} = (y_1, y_2, \dots, y_q)$, which denotes the q -variate response values, and the k -dimensional vector $\mathbf{x}$, which denotes the predictors. Suppose that the observation instances are $\tau_1 < \tau_2 < \dots < \tau_n$. The possibility that multiple observations are taken at a particular instance τ_i is not ruled out, and the successive observation instances do not need to be regularly spaced—that is, $(\tau_2 - \tau_1)$ does not need to equal $(\tau_3 - \tau_2)$. For $t = 1, 2, \dots, n$, suppose $p_t (\geq 1)$ denotes the number of observations recorded at instance τ_t . For notational simplicity, an integer-valued secondary index t is used to index the data so that $t = 1$ corresponds to $\tau = \tau_1$, $t = 2$ corresponds to $\tau = \tau_2$, and so on. Consider the following model:

$$\begin{aligned} \mathbf{Y}_t &= \mathbf{Z}_t \alpha_t + \mathbf{X}_t \beta + \epsilon_t && \text{Observation equation} \\ \alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + \mathbf{c}_{t+1} + \eta_{t+1} && \text{State transition equation} \\ \alpha_1 &= \mathbf{c}_1 + \mathbf{A}_1 \delta + \mathbf{W}_1 \gamma + \eta_1 && \text{Initial condition} \end{aligned}$$

The following list describes these equations:

- The *observation equation* describes the relationship between the $(p_t * q)$ -dimensional response vector $\mathbf{Y}_t$ and the unobserved vectors α_t , β , and ϵ_t . The q -variate responses are vertically stacked in a column to form this $(p_t * q)$ -dimensional response vector $\mathbf{Y}_t$. The m -dimensional vectors α_t are called *states*, the k -dimensional vector β is the regression coefficient vector associated with predictors $\mathbf{x}$, and the $(p_t * q)$ -dimensional vectors ϵ_t are called the *observation disturbances*. The matrices $\mathbf{Z}_t$ (of dimension $(q * p_t) \times m$) and $\mathbf{X}_t$ (of dimension $(q * p_t) \times k$) correspond to the *state effect* and the *regression effect*,

respectively. The elements of $\mathbf{X}_t$ are assumed to be fully known. The states $\boldsymbol{\alpha}_t$ and the disturbances $\boldsymbol{\epsilon}_t$ are *random* sequences. It is assumed that $\boldsymbol{\epsilon}_t$ is a sequence of independent, zero-mean, Gaussian random vectors with diagonal covariances, with the diagonal elements denoted by $\sigma_{t,i}^2, i = 1, 2, \dots, q * p_t$.

- The state sequence $\boldsymbol{\alpha}_t$ is assumed to follow a Markovian structure described by the state transition equation and the associated initial condition.
- The *state transition equation* postulates that a new instance of the state, $\boldsymbol{\alpha}_{t+1}$, is obtained by multiplying its previous instance, $\boldsymbol{\alpha}_t$, by an m -dimensional square matrix $\mathbf{T}_t$ (called the state transition matrix) and by adding three more terms: a known nonrandom vector $\mathbf{c}_{t+1}$ (called the state input); a regression term $\mathbf{W}_{t+1}\boldsymbol{\gamma}$, where $\mathbf{W}_{t+1}$ is an $m \times g$ -dimensional design matrix with fully known elements and $\boldsymbol{\gamma}$ is the g -dimensional regression vector; and a random disturbance vector $\boldsymbol{\eta}_{t+1}$. The m -dimensional state disturbance vectors $\boldsymbol{\eta}_t$ are assumed to be independent, zero-mean, Gaussian random vectors with covariances $\mathbf{Q}_t$ (not necessarily diagonal).
- The *initial condition* describes the starting condition of the state evolution equation. The starting state vector $\boldsymbol{\alpha}_1$ is assumed to be partially diffuse: it is the sum of a known nonrandom vector $\mathbf{c}_1$, a mean-zero Gaussian vector $\boldsymbol{\eta}_1$, and the terms $\mathbf{A}_1\boldsymbol{\delta}$ and $\mathbf{W}_1\boldsymbol{\gamma}$. $\mathbf{A}_1\boldsymbol{\delta}$ represents the contribution from a d -dimensional diffuse vector $\boldsymbol{\delta}$ (a diffuse vector is a Gaussian vector with infinite covariance). The observation and state regression vectors $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ are also assumed to be diffuse. The $m \times d$ matrix $\mathbf{A}_1$ is assumed to be completely known.
- The observation disturbances $\boldsymbol{\epsilon}_t$ and the state disturbances $\boldsymbol{\eta}_t$ (for $t \geq 1$) are assumed to be mutually independent. Either the elements of the matrices $\mathbf{Z}_t$, $\mathbf{T}_t$, and $\mathbf{Q}_t$ and the diagonal elements of the observation disturbance covariances $\sigma_{t,i}^2$ are assumed to be completely known, or some of them can be functions of a small set of unknown parameters (to be estimated from the data). Suppose that this unknown set of parameters is denoted by $\boldsymbol{\theta}$.
- The d -dimensional diffuse vector $\boldsymbol{\delta}$ from the state initial condition together with the observation and state regression vectors $\boldsymbol{\beta}$ and $\boldsymbol{\gamma}$ constitute the overall $(d + k + g)$ -dimensional diffuse initial condition of the model. For more information, see the section “[Filtering, Smoothing, Likelihood, and Structural Break Detection](#)” on page 767.

Although this description of the state space model might appear involved, it conveniently covers many variants of the SSMs that are encountered in practice and precisely describes the most general case that can be handled by the CSSM procedure. An important restriction about the preceding description of the model formulation is that it assumes that the matrices $\mathbf{X}_t$ and $\mathbf{W}_t$ that appear in the observation equation and the state equation respectively are free of unknown parameters and that the covariances of the observation disturbances $\boldsymbol{\epsilon}_t$ are diagonal. In most practical situations, the model under consideration can be easily reformulated to a statistically equivalent form that conforms to this restriction.

NOTE: The transition matrix $\mathbf{T}_t$ in the state equation relates the state $\boldsymbol{\alpha}_t$ at time t with the state $\boldsymbol{\alpha}_{t+1}$ at time $t + 1$. In many situations, such as when the observations are taken at irregular time intervals, $\mathbf{T}_t$ depends on information at both t and $t + 1$. Therefore, it is more appropriate to denote the transition matrix as $\mathbf{T}_t^{t+1}$. However, for simplicity, the former notation is used throughout this chapter. The same comment applies to the covariance matrix $\mathbf{Q}_t$ of the disturbance term $\boldsymbol{\eta}_t$.

For easy reference, [Table 14.4](#) summarizes the information contained in the SSM equations.

Table 14.4 State Space Model: Notation

Notation	Description
$\tau_1, \tau_2, \dots, \tau_n$	Distinct index values at which the observations are recorded
n	Number of distinct index instances
p_t	Number of observations recorded at index τ_t , $t = 1, 2, \dots, n$
q	Number of response variables in the model
$\mathbf{Y}_t = (y_{t,1}, y_{t,2}, \dots, y_{t,p_t * q})$	Vertically stacked vector of response values recorded at τ_t
$N = q * \sum_{t=1}^n p_t$	Total number of response values in the data set
k	Number of predictor (regressor) variables in the observation equation
$\mathbf{X}_t$	$(p_t * q) \times k$ matrix of predictor values recorded at τ_t
$\boldsymbol{\beta}$	k -dimensional regression vector that is associated with the predictors
$\boldsymbol{\epsilon}_t \sim N(0, (\sigma_{t,1}^2, \dots))$	$(q * p_t)$ -dimensional observation disturbance vector with diagonal covariance
m	Dimension of the state vectors $\boldsymbol{\alpha}_t$
$\boldsymbol{\alpha}_t$	m -dimensional state vector
$\mathbf{Z}_t$	$(q * p_t) \times m$ matrix that is associated with $\boldsymbol{\alpha}_t$ in the observation equation
$\mathbf{T}_t$	$m \times m$ state transition matrix
$\mathbf{c}_t$	m -dimensional state input vector
$\mathbf{W}_t$	$m \times g$ design matrix associated with $\boldsymbol{\gamma}$, the state regression vector
$\boldsymbol{\gamma}$	g -dimensional state regression vector
$\boldsymbol{\eta}_t \sim N(0, \mathbf{Q}_t)$	m -dimensional state disturbance vector
d	Dimension of the diffuse vector $\boldsymbol{\delta}$ in the state initial condition
$\boldsymbol{\delta} \sim N(0, \kappa \Sigma), \kappa \rightarrow \infty$	Diffuse vector in the state initial condition
$\mathbf{A}_1$	$m \times d$ constant matrix associated with $\boldsymbol{\delta}$
$\boldsymbol{\eta}_1 \sim N(0, \mathbf{Q}_1)$	m -dimensional state disturbance vector in the initial condition
$\boldsymbol{\theta}$	Parameter vector

Types of Sequence Data

The state space model specification in the CSSM procedure requires proper understanding of both the data organization and the form of the model. The SSMs that are appropriate for time series data might not be appropriate for irregularly spaced longitudinal data. The CSSM procedure distinguishes three types of data organization based on the way the observations are sequenced by the index variable. If an index variable is not specified, it is assumed that the observations are sequenced according to the observation number.

Regular: The observations are recorded at regularly spaced intervals; that is, $\tau_1, \tau_2, \dots, \tau_n$ are regularly spaced. Moreover, at each observation instance τ_i a single observation is recorded; that is, $p_t = 1$ for all t . The standard time series data (both univariate and multivariate) fall in this category.

Regular with Replication: The observations are recorded at regularly spaced intervals, but $p_t > 1$ for at least one t . Here the word replication is used loosely—it does not mean that the multiple observations at τ_t are replications in the precise statistical sense. The panel or cross-sectional data types fall into this category. In the panel data case with p cross sections, $p_t = p$ for all t .

Irregular: The observations are not recorded at regular intervals, and the number of observations p_t at each index instance can be different. The longitudinal data fall into this category.

It is not always easy to decide whether the specified model is appropriate for the given data type. Whenever possible, the CSSM procedure issues a note regarding the possible mismatch between the specified model and the data type being analyzed.

Overview of Model Specification Syntax

An SSM specification involves the description of the terms in the observation equation, the state transition equation, and the initial condition. For example, the response variables, the predictor variables, and the elements of the state transition matrix $\mathbf{T}_t$ must somehow be specified. The CSSM procedure syntax is designed so that little effort is needed to specify the more commonly needed models, while a highly flexible language is available for specifying more complex models. Two syntax features help achieve this goal: the ability to build a complex specification by combining simpler subspecifications, and a programming language for creating lists of variables to be used later in the model specification.

The CSSM procedure statements can be divided into two classes:

- **programming statements**, which are used to create lists of variables that can be used for a variety of purposes (for example, as the elements of the model system matrices)
- statements specific to the CSSM procedure that formulate the state space model and control its other aspects such as the input data specification and the resulting output

Since the matrices involved in the model specification can be specified as lists of variables, which you separately create by using the programming statements, you can finely control all aspects of the model specification. These programming statements permit the use of most DATA step language features such as the conditional logic (IF-THEN-ELSE), array type variables, and all the mathematical functions available in the DATA step. You can also use programming statements to define predictor variables on the fly.

Building a Complex Model Specification

In addition to being able to specify the system matrices in a flexible way, you can also build a complex model specification in a modular way by combining simpler subspecifications. Suppose that the state vector for the model to be specified is composed of subsections that are statistically independent, which is a common scenario in practical modeling situations. For example, suppose that $\boldsymbol{\alpha}_t$ can be divided into two disjoint subsections $\boldsymbol{\alpha}_t^a$ and $\boldsymbol{\alpha}_t^b$, which are statistically independent. This entails a corresponding block-diagonal structure to the system matrices $\mathbf{T}_t$, $\mathbf{W}_t$, and $\mathbf{Q}_t$ that govern the state equations. In this case the term $\mathbf{Z}_t \boldsymbol{\alpha}_t$ that appears in the observation equation also splits into the sum $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a + \mathbf{Z}_t^b \boldsymbol{\alpha}_t^b$ for appropriately partitioned matrices $\mathbf{Z}_t^a$ and $\mathbf{Z}_t^b$. The model specification syntax of the CSSM procedure makes building an SSM from such smaller pieces easy. Throughout this chapter, the linear combinations of the state subsections (such as $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$) that appear in the observation equation are called *components*. An SSM specification in the CSSM procedure is created by combining separate component specifications. In general, you specify a component in two steps: first you define a state subsection $\boldsymbol{\alpha}_t^a$, and then you define a matching linear combination $\mathbf{Z}_t^a \boldsymbol{\alpha}_t^a$. For some special components, such as some commonly needed *trend* components, you can combine these two steps into one keyword specification.

The following list summarizes the (nonprogramming) CSSM procedure syntax statements used for model specification:

- The **ID** statement specifies the index variable (τ). It is assumed that the data within each BY group are ordered (in ascending order) according to the ID variable. The CSSM procedure automatically creates a variable, `_ID_DELTA_`, which contains the difference between the successive ID values. This variable is available for use by the programming statements to define time-varying system matrices. For example, in the case of SSMs used for modeling the longitudinal data, the T_t and Q_t matrices often depend on `_ID_DELTA_` (see “[Example 14.5: A User-Defined Trend Model](#)” on page 823).
- The **PARMS** statement specifies variables that serve as the parameters of the model. That is, it partially defines the model parameter vector θ . Other elements of θ are implicitly defined if your specification of the system matrices is not fully complete.
- The **STATE** statement specifies a subsection of the model state vector. Multiple STATE statements can be used in the model specification; each one defines a statistically independent subsection of the model state vector. For full customization, T_t , W_t , and Q_t blocks that govern this subsection can be specified as lists of variables that are created by programming statements. However, you can obtain many commonly needed state subsection types simply by using the `TYPE=` option in this statement. For example, the use of `TYPE=SEASON(LENGTH=12)` results in a state subsection that can be used to define a monthly seasonal component.
- The **COMPONENT** statement specifies a linear combination that matches a state subsection that is previously defined in a STATE statement. Thus, a matching pair of STATE and COMPONENT statements define a component.
- The **TREND** statement is used for easy specification of some commonly needed components that follow stochastic patterns of certain predefined types.
- The **IRREGULAR** statement specifies the observation disturbance for a particular response variable.
- The **DEPLAG** statement specifies the terms in the model that involve lagged response variables.
- The **MODEL** statement specifies the observation equation for one of the response variables. A separate MODEL statement is needed for each response variable in the multivariate case. The MODEL statement specifies an equation in which the left-hand side is the response variable and the right-hand side is a list that contains components and regression variables.

Model Specification Steps

To illustrate the model specification steps, suppose y is a response variable and variables x_1 and x_2 are predictors. The following statements specify a model for y that includes two components named `cycle` and `randomWalk`, predictors x_1 and x_2 , and an observation disturbance named `whiteNoise`:

```
parms lambda / lower=(1.e-6) upper=(3.14);
parms cycleVar / lower=(1.e-6);
array cycleT{4} c1-c4;
c1 = cos(lambda);
c2 = sin(lambda);
c3 = -c2;
c4 = c1;
state s_cycle(2) T(g)=(cycleT) cov(I)=(cycleVar) a1(2);
component cycle=(1 0)*s_cycle;
trend randomWalk(rw);
```

```

irregular whiteNoise;
model y = x1 x2 randomWalk cycle whiteNoise;

```

The specification begins with a PARMs statement that defines two parameters, `lambda` and `cycleVar`, along with their lower and upper bounds (essentially 0 and π for `lambda`, and 0 and infinity for `cycleVar`). Next, programming statements define an array of variables, `cycleT`, which contains four variables, `c1`–`c4`; these variables are used later for defining the elements of the transition matrix of a state subsection. The STATE statement specifies the two-dimensional subsection `s_cycle`; the dimension appears within the parentheses after the name (`s_cycle(2)`). The T= option specifies the transition matrix for the `s_cycle` ($\mathbf{T}(\mathbf{g}) = (\mathbf{cycleT})$); the $\mathbf{g}$ in $\mathbf{T}(\mathbf{g})$ signifies that the form of the T matrix is *general*. The COV= option (`cov(I) = (cycleVar)`) specifies the covariance of the state disturbance ($\mathbf{Q}_t$ for $t \geq 2$); because of the use of $\mathbf{I}$ in `cov(I)`, the covariance is of the form scaled identity, essentially a two-dimensional diagonal matrix with both diagonal elements equal to `cycleVar`. The initial condition for `s_cycle` is completely diffuse because the A1= option, which specifies $\mathbf{A}_1$, specifies that the dimension of the diffuse vector $\boldsymbol{\delta}$ is 2: `a1(2)`. In this case there is no need to specify the covariance $\mathbf{Q}_1$ in the initial condition. The COMPONENT statement specifies the component `cycle`. It specifies `cycle` as a dot product of two vectors—(1 0) and `s_cycle`, which merely selects the first element of `s_cycle`: `component cycle = (1 0) * s_cycle`. The TREND statement defines a component named `randomWalk`; its type is *rw*, which signifies random walk. The IRREGULAR statement defines an observation disturbance named `whiteNoise`. Both the `randomWalk` and `whiteNoise` specifications are only partially complete—for example, the disturbance variance of `whiteNoise` is not specified. These unspecified variances, `trendVar`, which corresponds to `randomWalk`, and `wnVar`, which corresponds to `whiteNoise`, are automatically included in the list of unknown parameters, $\boldsymbol{\theta}$, along with the parameters that are defined by the PARMs statements. Thus, the parameter vector for this model is $\boldsymbol{\theta} = (\text{lambda } \text{cycleVar } \text{trendVar } \text{wnVar})$. Finally, the model specification is completed by the MODEL statement, which specifies the components of the observation equation: the response variable `y`, the predictors `x1` and `x2`, the components `randomWalk` and `cycle`, and the irregular term `whiteNoise`.

The preceding statements result in an SSM with a three-dimensional state vector, which is the result of combining the two-dimensional state subsection, `s_cycle`, and a one-dimensional subsection underlying the trend, `randomWalk`. In this specification, the initial state is completely diffuse with $\mathbf{Q}_1$ a null matrix, and $\mathbf{A}_1$ equal to the three-dimensional identity. The other state system matrices $\mathbf{T}_t$ and $\mathbf{Q}_t$ are time-invariant:

$$\mathbf{T} = \begin{bmatrix} \cos(\text{lambda}) & \sin(\text{lambda}) & 0 \\ -\sin(\text{lambda}) & \cos(\text{lambda}) & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad \mathbf{Q} = \begin{bmatrix} \text{cycleVar} & 0 & 0 \\ 0 & \text{cycleVar} & 0 \\ 0 & 0 & \text{trendVar} \end{bmatrix}$$

The observation equation is obvious with $\mathbf{Z} = [1 \ 0 \ 1]$.

Sparse Transition Matrix Specification

It often happens that the transition matrix $\mathbf{T}$ (or $\mathbf{T}_t$ in the time-varying case) specified in a STATE statement is sparse—that is, many of its elements are zero. The algorithms in the CSSM procedure exploit this sparsity for computational efficiency. In most cases the sparsity of a T-block can be inferred from the context. However, if the elements of the T-block are supplied by a list of variables in parentheses, it can be difficult to recognize elements that are structurally zero (this is because of the generality of the DATA step language used for defining the variables). To simplify the specification of such sparse transition matrix, CSSM procedure has adopted a convention: the variables that correspond to structural zeros can (and should) be left *unset*—that is, these variables are declared, but no value is assigned to them. As an example, suppose that a three-dimensional state subsection has the following form of transition matrix for some variables `X1`, `X2`, and `X3`

defined elsewhere in the program:

$$T = \begin{bmatrix} X1 & 0 & 0 \\ X2 & X1 & 0 \\ X3 & 0 & X1 \end{bmatrix}$$

The following (incomplete) statements show how to specify such a T-block:

```
array tMat{3,3};
do i=1 to 3;
    tMat[i, i] = x1;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
state foo(3) T(g)=(tMat) ...;
```

In this specification only the nonzero elements of the tMat array, which contains $3 \times 3 = 9$ elements, are assigned a value. On the other hand, the following statements show an alternate way of specifying the same T-block. This specification explicitly sets the zeros in the T-block (the elements above the diagonal and tMat[3,2]) to 0.

```
array tMat{3,3};
do i=1 to 3;
    do j=1 to 3;
        if i=j then tMat[i, j] = x1;
        else if j > i then tMat[i, j] = 0;
    end;
end;
tMat[2,1] = x2;
tMat[3,1] = x3;
tMat[3,2] = 0;
state foo(3) T(g)=(tMat) ...;
```

The first specification is simpler, and is preferred. The second specification is mathematically equivalent (and generates the same output) but is computationally less efficient since its sparsity structure cannot always be reliably inferred due to the generality of the DATA step language. In the first specification, the unset elements are recognized to be *structural* zeros while the set elements are treated as nonzero for sparsity purposes. For a simple illustration, see “[Example 14.5: A User-Defined Trend Model](#)” on page 823. Proper sparsity specification can lead to significant computational savings for larger matrices.

Regression Variable Specification in Multivariate Models

Suppose that a regression variable in a multivariate model affects two or more response variables. For example, suppose that response variables y1 and y2 depend on a regression variable x. This dependence can be categorized as one of two types:

- In the more common case, the regression coefficient of x for y1 and the regression coefficient of x for y2 are different. The relationship can be described as follows:

$$\begin{aligned} y1 &= \beta_1 x + \text{other terms} \\ y2 &= \beta_2 x + \text{other terms} \end{aligned}$$

In the CSSM procedure you can specify this type of relationship in two equivalent ways:

- You can specify the variable x in the MODEL statement for y_1 and specify the variable x_copy (a copy of x) in the MODEL statement for y_2 as follows:

```
x_copy = x;           /* create a copy of x */
model y1 = x ...;
model y2 = x_copy ...;
```

- You can specify the variable x in MODEL statements for both y_1 and y_2 as follows:

```
model y1 = x ...;
model y2 = x ...;
```

This specification avoids creating x_copy .

Of these two alternate ways, the first is preferred because x and x_copy can then be unambiguously used in an EVAL statement to refer to the terms $\beta_1 x$ and $\beta_2 x$, respectively.

- In the less common case, y_1 and y_2 share a common regression coefficient. The relationship can be described as follows:

$$\begin{aligned} y_1 &= \beta x + \text{other terms} \\ y_2 &= \beta x + \text{other terms} \end{aligned}$$

You can specify this type of relationship by placing the regression coefficient in the model state vector as follows:

```
state beta(1) T(I) A1(1) ;      /* beta is a constant state */
comp xeffect = beta*(x) ;
model y1 = xeffect ...;
model y2 = xeffect ...;
```

Here the STATE statement defines β as a one-dimensional, time-invariant constant (because the transition matrix is identity, the disturbance covariance is 0 and the initial state is diffuse). Next, the COMP statement defines $xeffect$ as the product between β and the variable x . Subsequently, both y_1 and y_2 use $xeffect$ in their respective MODEL statements.

Filtering, Smoothing, Likelihood, and Structural Break Detection

The Kalman filter and smoother (KFS) algorithm is the main computational tool for using SSM for data analysis. This subsection briefly describes the basic quantities generated by this algorithm and their relationship to the output generated by the CSSM procedure. For proper treatment of SSMs with a diffuse initial condition or when regression variables are present, a modified version of the traditional KFS, called diffuse Kalman filter and smoother (DKFS), is needed. A good discussion of the different variants of the traditional and diffuse KFS can be found in Durbin and Koopman (2012). The DKFS implemented in the CSSM procedure closely follows the treatments in De Jong and Chu-Chun-Lin (2003) and Francke, Koopman, and de Vos (2010). Additional details can be found in these references.

The state space model equations (see the section “[State Space Model and Notation](#)” on page 760) imply that the combined response data vector $\mathbf{Y} = (\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_n)$ has a Gaussian probability distribution. This

probability distribution is *proper* if d , the dimension of the diffuse vector δ in the initial condition, is 0 and if $(k + g)$, the total number of regression variables in the observation and state equations, is also 0 (the regression vectors β and γ are also treated as a diffuse vectors). Otherwise, this probability distribution is *improper*. The KFS algorithm is a combination of two iterative phases: a forward pass through the data, called *filtering*, and a backward pass through the data, called *smoothing*, that uses the quantities generated during filtering. One of the advantages of using the SSM formulation to analyze the time series data is its ability to handle the missing values in the response variables. The KFS algorithm appropriately handles the missing values in $\mathbf{Y}$. For additional information about how PROC CSSM handles missing values, see the section “Missing Values” on page 793.

Filtering Pass

The filtering pass sequentially computes the quantities shown in Table 14.5 for $t = 1, 2, \dots, n$ and $i = 1, 2, \dots, q * p_t$.

Table 14.5 KFS: Filtering Phase

Quantity	Description
$\hat{y}_{t,i} = E(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the response values
$v_{t,i} = y_{t,i} - \hat{y}_{t,i}$	One-step-ahead prediction residuals
$F_{t,i} = \text{Var}(y_{t,i} y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Variance of the one-step-ahead prediction
$\hat{\alpha}_{t,i} = E(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	One-step-ahead prediction of the state vector
$\mathbf{P}_{t,i} = \text{Cov}(\alpha_t y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$	Covariance of $\hat{\alpha}_{t,i}$
$\mathbf{b}_{t,i}$	$(d + k + g)$ -dimensional vector
$\mathbf{S}_{t,i}$	$(d + k + g)$ -dimensional symmetric matrix
$\begin{pmatrix} \hat{\delta} & \hat{\beta} & \hat{\gamma} \end{pmatrix}_{t,i}' = \mathbf{S}_{t,i}^{-1} \mathbf{b}_{t,i}$	Estimates of δ , β , and γ by using the data up to (t, i)
$\mathbf{S}_{t,i}^{-1}$	Covariance of $\begin{pmatrix} \hat{\delta} & \hat{\beta} & \hat{\gamma} \end{pmatrix}_{t,i}'$
$\mathbf{S}_{t,i}^*$	$(d + k + g)$ -dimensional symmetric matrix needed in the marginal likelihood computation

Here the notation $E(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the *conditional expectation* of $y_{t,i}$ given the history up to the index $(t, i - 1)$: $(y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$. Similarly $\text{Var}(y_{t,i} | y_{t,i-1}, \dots, y_{t,1}, \mathbf{Y}_{t-1}, \dots, \mathbf{Y}_1)$ denotes the corresponding conditional variance. The quantity $v_{t,i} = y_{t,i} - \hat{y}_{t,i}$ is set to missing whenever $y_{t,i}$ is missing. Note that $\hat{y}_{t,i}$ are *one-step-ahead* forecasts only when the model has only one response variable and the data are a time series; in all other cases it is more appropriate to call them *one-measurement-ahead* forecasts (since the next measurement might be at the same time point). Despite this, $\hat{y}_{t,i}$ are called one-step-ahead predictions (and $v_{t,i}$ are called one-step-ahead residuals) throughout this document. In the diffuse case, the conditional expectations must be appropriately interpreted. The vector $\mathbf{b}_{t,i}$ and the matrix $\mathbf{S}_{t,i}$ contain some accumulated quantities that are needed for the estimation of δ , β , and γ . Of course, when $(d + k + g) = 0$ (the nondiffuse case), these quantities are not needed. In the diffuse case, because the matrix $\mathbf{S}_{t,i}$ is sequentially accumulated (starting at $t = 1, i = 1$), it might not be invertible until some $t = t_*, i = i_*$. The filtering process is called *initialized* after $t = t_*, i = i_*$. In some situations, this initialization might not happen even after the entire sample is processed—that is, the filtering process remains *uninitialized*. This can happen if the regression variables are collinear or if the data are not sufficient to estimate the initial condition δ for some other reason. In

the diffuse case if the marginal likelihood is to be computed (see the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769), an additional matrix ($\mathbf{S}_{t,i}^*$) is computed at each step by sequential accumulation.

The filtering process is used for a variety of purposes. One important use of filtering is to compute the likelihood of the data. In the model-fitting phase, the unknown model parameters θ are estimated by maximum likelihood. This requires repeated evaluation of the likelihood at different trial values of θ . After θ is estimated, it is treated as a known vector. The filtering process is used again with the fitted model in the forecasting phase, when the one-step-ahead forecasts and residuals based on the fitted model are provided. In addition, this filtering output is needed by the smoothing phase to produce the full-sample component estimates and for the structural break analysis.

Likelihood Computation and Model-Fitting Phase

Because of the Gaussian nature of the response vector, the likelihood of $\mathbf{Y}$ can be computed by using the prediction-error decomposition. The desired prediction-error decomposition is obtained by the filtering pass described in the previous section (“[Filtering Pass](#)” on page 768). When the state space model under consideration has a nondiffuse initial condition and no regression effects are present in the observation and state equations, $\mathbf{Y}$ has a proper Gaussian distribution and its likelihood is defined unambiguously. Otherwise, the definition of the likelihood depends on the treatment of the diffuse quantities— δ , β , and γ . Francke, Koopman, and de Vos (2010) describe three variants of the likelihood function—*diffuse*-likelihood, *marginal*-likelihood, and *profile*-likelihood—that are commonly considered for state space models that have a diffuse initial condition. In the CSSM procedure, you can either use diffuse likelihood ($L_d(\mathbf{Y}, \theta)$) or marginal likelihood ($L_m(\mathbf{Y}, \theta)$) for parameter estimation. By default, diffuse likelihood is used for parameter estimation.

In terms of the quantities described in [Table 14.5](#), diffuse, marginal, and profile likelihoods are defined as follows:

$$\begin{aligned} -2 \log L_d(\mathbf{Y}, \theta) &= N_0 \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n} + \log(|\mathbf{S}_{n,p_n}|) \\ -2 \log L_m(\mathbf{Y}, \theta) &= N_0 \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n} + \log(|\mathbf{S}_{n,p_n}|) \\ &\quad - \log(|\mathbf{S}_{n,p_n}^*|) \\ -2 \log L_p(\mathbf{Y}, \theta) &= N \log 2\pi + \sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\log F_{t,i} + \frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}_{n,p_n}' \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n} \end{aligned}$$

In the preceding formulas, the terms that are associated with the missing response values $y_{t,i}$ are excluded and N denotes the total number of nonmissing response values in the sample. In addition, $N_0 = (N - k - g - d)$; $|\mathbf{S}_{n,p_n}|$ and $|\mathbf{S}_{n,p_n}^*|$ denote the determinants of $\mathbf{S}_{n,p_n}$ and $\mathbf{S}_{n,p_n}^*$, respectively; and $\mathbf{b}_{n,p_n}'$ denotes the transpose of the column vector $\mathbf{b}_{n,p_n}$. If $\mathbf{S}_{n,p_n}$ is not invertible, then a generalized inverse is used in place of $\mathbf{S}_{n,p_n}^{-1}$, and $|\mathbf{S}_{n,p_n}|$ and $|\mathbf{S}_{n,p_n}^*|$ are computed based on the nonzero eigenvalues of $\mathbf{S}_{n,p_n}$ and $\mathbf{S}_{n,p_n}^*$, respectively. Moreover, in this case, $N_0 = N - \text{Rank}(\mathbf{S}_{n,p_n})$. When $(d + k + g) = 0$, the terms that involve $\mathbf{S}_{n,p_n}$, $\mathbf{S}_{n,p_n}^*$, and $\mathbf{b}_{n,p_n}$ are absent.

The expression for marginal likelihood is derived by treating the diffuse quantities as fixed but unknown parameters. The expression can be shown to be based on a linear transformation of the N -dimensional response vector $\mathbf{Y}$. For a suitably chosen $N \times N$ matrix $\mathbf{H}$, let $\mathbf{U} = \mathbf{H}\mathbf{Y}$. $\mathbf{H}$ is chosen such that the

N -dimensional transformed vector $\mathbf{U}$ partitions into two uncorrelated (and independent because of their Gaussian nature) subvectors: an N_0 -dimensional vector $\mathbf{U}_1$ and a $(d + k + g)$ -dimensional vector $\mathbf{U}_2$. Furthermore, the distribution of $\mathbf{U}_1$ does not depend on the diffuse vectors $(\boldsymbol{\delta}, \boldsymbol{\beta}, \text{ and } \boldsymbol{\gamma})$, and $\mathbf{U}_2$ stores the generalized least squares estimates of the diffuse vectors: $\mathbf{U}_2' = (\hat{\boldsymbol{\delta}} \ \hat{\boldsymbol{\beta}} \ \hat{\boldsymbol{\gamma}})'$. It turns out that the N_0 -dimensional vector, $\mathbf{U}_1$, has a proper Gaussian distribution and the marginal likelihood, $\log \mathbf{L}_m(\mathbf{Y}, \boldsymbol{\theta})$, is the proper likelihood of $\mathbf{U}_1$. The diffuse likelihood, $\log \mathbf{L}_d(\mathbf{Y}, \boldsymbol{\theta})$, is also based on $\mathbf{U}_1$. However, rather than assuming the diffuse quantities as unknown parameters, the expression of the diffuse likelihood is derived by assuming that $\boldsymbol{\delta}$, $\boldsymbol{\beta}$, and $\boldsymbol{\gamma}$ are random vectors with diffuse priors. Even though the marginal and diffuse likelihoods are based on different interpretations of the diffuse quantities, their expressions differ by only one term: the diffuse likelihood does not have the term $-\log(|\mathbf{S}_{n,p_n}^*|)$. Since the marginal likelihood is the proper likelihood of $\mathbf{U}_1$, the diffuse likelihood can be interpreted as a quasi-likelihood of $\mathbf{U}_1$. Apart from being essential to make it a proper likelihood, the extra term in the marginal likelihood plays another useful role: it makes the marginal likelihood invariant to linear rescaling of the diffuse effects, a desirable property in a likelihood. The diffuse likelihood is not invariant to linear rescaling of the diffuse effects. The profile likelihood, $\log \mathbf{L}_p(\mathbf{Y}, \boldsymbol{\theta})$, is the likelihood of the response vector $\mathbf{Y}$ evaluated at the generalized least squares estimates of the diffuse vectors: $(\boldsymbol{\delta} \ \boldsymbol{\beta} \ \boldsymbol{\gamma})' = (\hat{\boldsymbol{\delta}} \ \hat{\boldsymbol{\beta}} \ \hat{\boldsymbol{\gamma}})'$. It is derived by treating the diffuse quantities as fixed but unknown parameters and, like the marginal likelihood, is invariant to linear rescaling of the diffuse effects. For an illustration of this invariance property, see “[Example 14.18: Invariance of the Marginal Likelihood under Linear Rescaling of the Diffuse Effects](#)” on page 891.

In the literature, the marginal likelihood (in addition to the diffuse likelihood) is also called the *restricted*-likelihood, and the estimate of the parameter vector $\boldsymbol{\theta}$ that is obtained by maximizing $\log \mathbf{L}_m(\mathbf{Y}, \boldsymbol{\theta})$ (or $\log \mathbf{L}_d(\mathbf{Y}, \boldsymbol{\theta})$) is called the restricted maximum likelihood estimate (REML). In this section, the REML estimate that is based on marginal likelihood is denoted by REML_M and the REML estimate that is based on diffuse likelihood is denoted by REML_D. In addition, the estimate of $\boldsymbol{\theta}$ that is obtained by maximizing the profile likelihood is called the maximum likelihood estimate (ML). In the absence of the diffuse quantities, all three likelihoods are the same and the REML_M, REML_D, and ML estimates coincide. When diffuse quantities are present, there is some evidence to prefer REML_M, the estimate of $\boldsymbol{\theta}$ that is based on the marginal likelihood. For more information, see Francke, Koopman, and de Vos (2010) and the references therein. By default, the CSSM procedure uses diffuse likelihood for parameter estimation. You can switch to marginal likelihood by using the `LIKE=MARGINAL` option in the PROC CSSM statement. In the current release of the CSSM procedure, you cannot request parameter estimation by using profile likelihood.

Interestingly, for many types of state space models, REML_M and REML_D coincide even when diffuse effects are present. This is because for these models the extra term in the marginal likelihood, $-\log(|\mathbf{S}_{n,p_n}^*|)$, turns out to be independent of the parameter vector $\boldsymbol{\theta}$. Specifically, for models that are specified by using the PROC CSSM syntax, REML_M and REML_D differ only if at least one of the following conditions hold:

- The transition matrix ($\mathbf{T}_t$) that is implied by a STATE statement depends on at least one unknown parameter and the diffuse dimension of the associated state subsection is nonzero.
- The list of variables that is specified in a COMPONENT statement depends on at least one unknown parameter and the diffuse dimension of the associated state subsection is nonzero.
- At least one lag term in a DEPLAG statement depends on an unknown parameter.
- A TREND statement with GROWTH or GROWTH(OU) type is present and the growth parameter, ϕ , is unknown.

In particular, if the parameter vector affects only the disturbance covariances (Q_t) in the state equation and the error variances ($\sigma_{t,i}^2$) in the observation equation (see [Table 14.4](#)), REML_M and REML_D coincide. These observations also imply that REML_M and REML_D coincide for the most commonly used univariate and multivariate unobserved component models and for ARIMA models, with or without regression effects.

NOTE: For many examples in the section “[Examples: CSSM Procedure](#)” on page 803, one of the preceding conditions does hold and the REML_M and REML_D estimates do differ. However, in all these cases, it turns out that the differences in REML_M and REML_D are not large enough to change the overall conclusions of the analysis. As verification, you can rerun the analyses that are described in “[Example 14.10: A Transfer Function Model for the Gas Furnace Data](#)” on page 853, “[Example 14.13: Bivariate Model for Sales of Mink and Muskrat Furs](#)” on page 871, and “[Example 14.14: A Factor Model for Now-Casting the US Economy](#)” on page 876 by using the `LIKE=MARGINAL` option in the PROC CSSM statement. Of course, this will not be true in general.

The REML_D and REML_M estimates of the unknown parameter vector θ (each denoted as $\hat{\theta}$), are computed by maximizing the diffuse (or marginal) likelihood. This is done by using a nonlinear optimization process that involves repeated evaluations of $L_d(Y, \theta)$ (or $L_m(Y, \theta)$) at different values of θ . Approximate standard errors of $\hat{\theta}$ are computed by taking the square root of the diagonal elements of its (approximate) covariance matrix. This covariance is computed as $-\mathbf{H}^{-1}$, where $\mathbf{H}$ is the Hessian (the matrix of the second-order partials) of $\log L_d(Y, \theta)$ (or $\log L_m(Y, \theta)$) evaluated at the optimum $\hat{\theta}$. It is known that under mild regularity assumptions (as the number of distinct time points tends toward infinity), $\hat{\theta}$ is consistent and efficient. For good discussions about REML_D, REML_M, and ML estimates, see Searle, Casella, and McCulloch (1992); Laird (2004); Francke, Koopman, and de Vos (2010).

If the marginal likelihood is used for parameter estimation, the CSSM procedure reports the values of all three likelihoods at the parameter estimate $\hat{\theta}$. Otherwise, PROC CSSM reports the values of the diffuse and profile likelihoods that are calculated at the parameter estimate $\hat{\theta}$. Let $\dim(\theta)$ denote the dimension of the parameter vector θ . After PROC CSSM completes the parameter estimation, it prints the “Likelihood Computation Summary” table, which summarizes the likelihood calculations at $\hat{\theta}$, as shown in [Table 14.6](#).

Table 14.6 Likelihood Computation Summary

Quantity	Formula
Nonmissing response values used	N
Estimated parameters	$\dim(\theta)$
Initialized diffuse state elements	$\text{rank}(\mathbf{S}_{n,p_n})$
Normalized residual sum of squares	$\sum_{t=1}^n \sum_{i=1}^{q \cdot p_t} \left(\frac{v_{t,i}^2}{F_{t,i}} \right) - \mathbf{b}'_{n,p_n} \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$
Diffuse log likelihood	$\log L_d(Y, \hat{\theta})$
Marginal log likelihood	$\log L_m(Y, \hat{\theta})$
Profile log likelihood	$\log L_p(Y, \hat{\theta})$

In addition to the likelihood computation summary, PROC CSSM also reports the information criteria that are based on the diffuse and profile likelihoods. It also reports the information criteria that are based on the marginal likelihood if marginal likelihood is used for parameter estimation. A variety of information criteria are reported. All these criteria are functions of twice the negative likelihood ($-2 \log \mathbf{L}$, where the likelihood can be diffuse, marginal, or profile), N_* (the effective sample size), and $nparm$ (the effective number of model parameters). For information criteria that are based on the diffuse and marginal likelihoods,

the effective sample size, N_* , is equal to N_0 and the effective number of model parameters, $nparm$, is equal to $\dim(\theta)$. For information criteria that are based on the profile likelihood, the effective sample size, N_* , is equal to N and the effective number of model parameters, $nparm$, is equal to $\dim(\theta) + d + k + g$. Table 14.7 summarizes the reported information criteria in smaller-is-better form.

Table 14.7 Information Criteria

Criterion	Formula	Reference
AIC	$-2 \log \mathbf{L} + 2nparm$	Akaike (1974)
AICC	$-2 \log \mathbf{L} + 2nparm N_*/(N_* - nparm - 1)$	Hurvich and Tsai (1989) Burnham and Anderson (1998)
HQIC	$-2 \log \mathbf{L} + 2nparm \log \log(N_*)$	Hannan and Quinn (1979)
BIC	$-2 \log \mathbf{L} + nparm \log(N_*)$	Schwarz (1978)
CAIC	$-2 \log \mathbf{L} + nparm(\log(N_*) + 1)$	Bozdogan (1987)

Forecasting Phase

After the model-fitting phase, the filtering process is repeated again to produce the model-based one-step-ahead response variable forecasts ($\hat{y}_{t,i}$), residuals ($v_{t,i}$), and their standard errors ($\sqrt{F_{t,i}}$). In addition, one-step-ahead forecasts of the components that are specified in the MODEL statements, and any other user-defined linear combinations of α_t , are also produced. These forecasts are set to missing as long as the index $t < t_*$ (that is, until the filtering process is initialized). If the filtering process remains uninitialized, then all the quantities that are related to the one-step-ahead forecast (such as $\hat{y}_{t,i}$ and $v_{t,i}$) are reported as missing. When the fitted model is appropriate, the one-step-ahead residuals $v_{t,i}$ form a sequence of uncorrelated normal variates. This fact can be used during model diagnostic process.

Smoothing Phase

After the filtering phase of KFS produces the one-step-ahead predictions of the response variables and the underlying state vectors, the smoothing phase of KFS produces the full-sample versions of these quantities—that is, rather than using the history up to $(t, i - 1)$, the entire sample $\mathbf{Y}$ is used. The smoothing phase of KFS is a backward algorithm, which begins at $t = n$ and $i = q * p_n$ and goes back toward $t = 1$ and $i = 1$. It produces the following quantities:

Table 14.8 KFS: Smoothing Phase

Quantity	Description
$\tilde{y}_{t,i} = E(y_{t,i} \mathbf{Y})$	Interpolated response value
$\tilde{F}_{t,i} = \text{Var}(y_{t,i} \mathbf{Y})$	Variance of the interpolated response value
$\tilde{\alpha}_t = E(\alpha_t \mathbf{Y})$	Full-sample estimate of the state vector
$\tilde{\mathbf{P}}_t = \text{Cov}(\alpha_t \mathbf{Y})$	Covariance of $\tilde{\alpha}_t$
$\begin{pmatrix} \tilde{\delta} & \tilde{\beta} & \tilde{\gamma} \end{pmatrix}' = \mathbf{S}_{n,p_n}^{-1} \mathbf{b}_{n,p_n}$	Full-sample estimates of δ , β , and γ
$\mathbf{S}_{n,p_n}^{-1}$	Covariance of $\begin{pmatrix} \tilde{\delta} & \tilde{\beta} & \tilde{\gamma} \end{pmatrix}'$

Note that if $y_{t,i}$ is not missing, then $\tilde{y}_{t,i} = E(y_{t,i}|\mathbf{Y}) = y_{t,i}$ and $\tilde{F}_{t,i} = \text{Var}(y_{t,i}|\mathbf{Y}) = 0$ because $y_{t,i}$ is completely known, given $\mathbf{Y}$. Therefore, $\tilde{y}_{t,i}$ provides nontrivial information only when $y_{t,i}$ is missing—in which case $\tilde{y}_{t,i}$ represents the best estimate of $y_{t,i}$ based on the available data. The full-sample estimates of components that are specified in the model equations are based on the corresponding linear combinations of $\tilde{\alpha}_t$. Similarly, their standard errors are computed by using appropriate functions of $\tilde{\mathbf{P}}_t$.

If the filtering process remains uninitialized until the end of the sample (that is, if $\mathbf{S}_{n,p_n}$ is not invertible), some linear combinations of δ , β , and γ are not estimable. This, in turn, implies that some linear combinations of α_t are also inestimable. These inestimable quantities are reported as missing. For more information about the estimability of the state effects, see Selukar (2010).

Delete-One Cross Validation and Structural Breaks

In addition to the interpolation of missing response values and the full-sample estimation of components in the model, the smoothing phase can also produce several useful diagnostic measures that can indicate outlying observations and breaks in the state evolution process. The treatment of additive outliers and structural breaks that is described in this section is based on De Jong and Penzer (1998). Also see Selukar (2017) for illustrative examples.

Delete-One Cross Validation and the Additive Outlier Detection

Let $\text{AO}_{t,i} = y_{t,i} - E(y_{t,i}|\mathbf{Y}^{t,i})$ denote the difference between the observed response value $y_{t,i}$ and its estimate or prediction by using all the data except $y_{t,i}$, which is denoted by $\mathbf{Y}^{t,i}$. The smoothing phase of DKFS can generate $\text{AO}_{t,i}$ (and its variance) at all (t, i) . A large value of $\text{AO}_{t,i}$ signifies that the observed response value ($y_{t,i}$) is unusual relative to the rest of the sample (according to the postulated model). Such values are called additive outliers. In the literature, $\text{AO}_{t,i}$ are referred by a few different names. Sometimes they are called *delete-one cross validation errors* or simply *prediction errors*. In this chapter, these names are used interchangeably. Like the one-step-ahead residuals, $v_{t,i}$, the prediction errors can be used in checking the adequacy of the model. The prediction errors are normally distributed; however, unlike $v_{t,i}$, they are not serially uncorrelated. $\text{AO}_{t,i}$ is set to missing when $y_{t,i}$ is missing. The CSSM procedure prints a summary table of extreme additive outliers by default. In addition, you can request the plotting of the standardized prediction errors, and they can be output to a data set.

The prediction error sum of squares (PRESS)

$$\sum_{t,i} \text{AO}_{t,i}^2$$

can be a useful measure of fit to compare different models. It is also called the *cross validation error sum of squares*. An additional measure of fit based on the prediction errors is called the *generalized cross validation error sum of squares* (GCV). Denoting the variance of $\text{AO}_{t,i}$ by $\text{VAR_AO}_{t,i}$, it is defined as

$$\frac{\sum_{t,i} (\text{AO}_{t,i}^2 / \text{VAR_AO}_{t,i})}{[\sum_{t,i} (1 / \text{VAR_AO}_{t,i})]^2}$$

You can request the printing of PRESS and GCV by specifying the PRESS option in the OUTPUT statement.

After inspecting the reported additive outliers, you can adjust the model to account for the effects of some of the extreme outlying observations. This can be done by including appropriate dummy variables in the observation equation.

Structural Breaks in the State Evolution

The additive outliers that are discussed in the preceding section are diagnostic measures associated with the measurement equation. The smoothing phase of DKFS can generate diagnostic measures that are also associated with the state equation.

For simplicity of notation and exposition, initially assume that the state equation has the following form:

$$\alpha_{t+1} = \mathbf{T}_t \alpha_t + \mathbf{c}_{t+1} + \eta_{t+1}$$

That is, the state regression term $\mathbf{W}_{t+1}\gamma$ is absent in the postulated model. Suppose that an unanticipated change of unknown size takes place in the i_0 th element of the state at time $(t_0 + 1)$. The model can then be adjusted to account for this change by including a suitable dummy regressor in the state equation as follows:

$$\alpha_{t+1} = \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1}\gamma + \mathbf{c}_{t+1} + \eta_{t+1}$$

Here $\mathbf{W}_t$ is a sequence of m -dimensional column vectors such that $\mathbf{W}_{t_0+1}[i_0] = 1$ and $\mathbf{W}_t[i] = 0$ for all other t and i . The estimate of the regression coefficient γ provides information about the size of the unanticipated change in the i_0 th element of α_t at time $t = t_0 + 1$. Similarly, an unanticipated change in a subsection of α_t at a time $t = t_0 + 1$ can be estimated by using a set of appropriate dummies (the number of dummies equals the number of elements in the state subsection) in the state equation. The algorithm of De Jong and Penzer (1998) efficiently generates the estimates of such one-time changes in the state at all distinct time points in the sample in one smoothing pass. A statistically significant value of γ at a time point t_0 indicates an unanticipated change in the relevant element (or the subsection) of α_{t_0} . Note that the change associated with an additive outlier is temporary: the previous or the subsequent measurements are not affected. On the other hand, because of the evolutionary nature of the state equation, a one-time change in the state affects all the subsequent states, which in turn affect the subsequent observations. In this sense, a significant unanticipated change in the state is a *structural break*.

In the preceding discussion, the absence of the state regression variables in the postulated model was assumed only for notational simplicity. If the postulated model does contain some state regression variables, the dummy variable that is associated with the one-time state change is simply added to the existing set of state regression variables, and the interpretation of its regression coefficient as the measure of unanticipated change in the state remains unaffected.

In the CSSM procedure, you can request the computation of significance statistics that are associated with one-time changes in the state subsections specified by using the STATE statement in addition to the state subsections that are associated with the components specified by using the TREND statements. This is done by using the CHECKBREAK option in these statements. In addition, you can request the computation of such statistics for the entire state α_t by using the MAXSHOCK option in the OUTPUT statement. The significance statistics can be computed for both elementwise change and subsectionwise change. The computation of subsectionwise change statistics can be computationally expensive for large subsections (an inversion of a $p \times p$ -dimensional matrix at each distinct time point in the sample is needed for the computation of significance statistics for a state subsection of size p). For an example of structural break analysis, see “[Example 14.8: Diagnostic Plots and Structural Break Analysis](#)” on page 841.

Estimation of User-Specified Linear Combination of State Elements

By default, the CSSM procedure computes the estimates of all the components that are specified in the MODEL statements (you can print these estimates by using the PRINT= option in the respective TREND and COMPONENT statements, or you can output these estimates to a data set by specifying it in the OUT= option in the OUTPUT statement). However, in many cases it is desirable to obtain the estimates of additional linear combinations of the state elements and the regression effects. The CSSM procedure provides two statements, the COMPONENT statement and the EVAL statement, that are useful for specifying virtually any desired linear combination of the elements of the state vector and the regression effects in the observation equation. After a desired linear combination is specified, you can print or output its estimate as you would for a component that is used in the MODEL statement. This feature of the CSSM procedure is illustrated in many examples in the section “Examples: CSSM Procedure” on page 803. For example, in the second part of “Example 14.4: Smoothing of Repeated Measures for Longitudinal Data” on page 814, the COMPONENT and EVAL statements are used to define the contrasts between the growth profiles of cows that are receiving different treatments. Similarly, in “Example 14.7: A Dynamic Factor Model for the Yield Curve” on page 831, the EVAL statement is used to define the yield curve as a sum of the components that are used in the MODEL statement.

Contrasting PROC CSSM with Other SAS Procedures

The CSSM procedure complements several SAS/ETS procedures and the MIXED procedure in SAS/STAT software (see Chapter 84, “The MIXED Procedure” (*SAS/STAT User’s Guide*)). The statistical models underlying all these procedures can be formulated as state space models; however, in many cases this formulation effort can be considerable. Generally speaking, when a problem can be formulated and satisfactorily solved either by using the CSSM procedure or by using one of these other procedures, the other procedures are likely to be more efficient. However, in many instances, the CSSM procedure can solve more general problems or offer more detailed analysis, or both. Throughout this discussion, it is assumed that the problem being solved can be modeled as a linear statistical model with Gaussian response variables. In particular, situations that require models such as autoregressive conditional heteroscedasticity (ARCH) models, and models with categorical response variables are not considered. The following list provides a more specific comparison of the CSSM procedure with different procedures:

- All the SAS/ETS time series analysis procedures (the ARIMA, ESM, UCM, VARMAX, STATESPACE, and PANEL procedures) require time series data and are not applicable to the longitudinal data.
- For univariate time series analysis, the modeling facilities provided by the ARIMA, ESM, and UCM procedures are adequate in most cases. The CSSM procedure can handle cases that do not fit neatly into one of these categories.
- For multivariate time series data analysis, you can use the VARMAX procedure for vector ARIMA modeling and the STATESPACE procedure for state space modeling. The capabilities of the CSSM procedure are complementary to these procedures. In particular, the predefined multivariate structural models available in the CSSM procedure cannot be specified by either of these procedures. In addition, you can formulate a much wider range of multivariate models—for example, models for series with different frequencies, by using the CSSM procedure.

- When the $\mathbf{R}$ side effects are not too complicated (for example, if $\mathbf{R}$ is diagonal), the model considered by the MIXED procedure is a special case of the model considered by the CSSM procedure. In the case of diagonal $\mathbf{R}$, it is easy to see that the state vector $\boldsymbol{\alpha}_t$ is equal to $\boldsymbol{\gamma}$, the MIXED random-effects vector, for all $t \geq 1$ (that is, $\boldsymbol{\alpha}_t$ is *time invariant*). Therefore, the random-effects MIXED model is obtained by setting $\mathbf{T} = \text{Identity}$, $\mathbf{Q}_t = \mathbf{0}$, $t \geq 2$, $\mathbf{Q}_1 = \mathbf{G}$ (the MIXED $\mathbf{G}$ matrix), and $\mathbf{A}_1 = \mathbf{0}$.
- For the analysis of cross-sectional data, you can use the PANEL procedure. In this case, the CSSM procedure capabilities are complementary. PROC CSSM can provide alternate models, REML estimates, richer missing value support, and the estimates of the unobserved components (see the section “Getting Started: CSSM Procedure” on page 722 and the examples “Example 14.2: Random-Effects and Autoregressive Models for Panel Data” on page 809 and “Example 14.11: Dynamic Panel Model for the Cigar Data” on page 859 for more information). In some situations the cross-sectional studies contain many panels but very few distinct time points. The PANEL procedure based analysis is better suited in such settings. In order for the analysis based on PROC CSSM to be valid, the cross-sectional study must contain an adequate number of distinct time points.

Predefined Trend Models

The statistical models that govern the predefined trend components available in the CSSM procedure are divided into two groups: models that are applicable to equally spaced data (possibly with replication), and models that are applicable more generally (the irregular data type). Each trend component can be described as a dot product $\mathbf{Z}\boldsymbol{\alpha}_t$ for some (time-invariant) vector $\mathbf{Z}$ and a state vector $\boldsymbol{\alpha}_t$. The component specification is complete after the vector $\mathbf{Z}$ is specified and the system matrices that govern the equations of $\boldsymbol{\alpha}_t$ are specified. For trend models for regular data, all the system matrices are time-invariant. For irregular data, $\mathbf{T}_t$ and $\mathbf{Q}_t$ depend on the spacing between the distinct time points: $(\tau_{t+1} - \tau_t)$.

Trend Models for Regular Data

These models are applicable when the data type is either regular or regular with replication. A good reference for these models is Harvey (1989).

Random Walk Trend

This model provides a trend pattern in which the level of the curve changes with time. The rapidity of this change is inversely proportional to the disturbance variance σ^2 that governs the underlying state. It can be described as $\mathbf{Z}\boldsymbol{\alpha}_t$, where $\mathbf{Z} = (1)$ and the (one-dimensional) state α_t follows a random walk:

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}, \quad \eta_t \sim N(0, \sigma^2)$$

Here $\mathbf{T} = 1$ and $\mathbf{Q} = \sigma^2$. The initial condition is fully diffuse. Note that if $\sigma^2 = 0$, the resulting trend is a fixed constant.

Local Linear Trend

This model provides a trend pattern in which both the level and the slope of the curve change with time. This variation in the level and the slope is controlled by two parameters: σ_1^2 controls the level variation, and σ_2^2 controls the slope variation. If $\sigma_1^2 = 0$, the resulting trend is called an *integrated random walk*. If both $\sigma_1^2 = 0$ and $\sigma_2^2 = 0$, then the resulting model is the deterministic linear time trend. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ 1)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is fully diffuse.

Damped Local Linear Trend

This trend pattern is similar to the local linear trend pattern. However, in the DLL trend the slope follows a first-order autoregressive model, whereas in the LL trend the slope follows a random walk. The autoregressive parameter or the damping factor, ϕ , must lie between 0.0 and 1.0, which implies that the long-run forecast according to this pattern has a slope that tends to 0. Here $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ 1, \ 0 \ \phi)$, and $\mathbf{Q} = \text{Diag}(\sigma_1^2, \sigma_2^2)$. The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \sigma_2^2/(1 - \phi * \phi))$.

ARIMA Trend

This section describes the state space form for a component that follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model. The notation for ARIMA models is explained in the **TREND** statement.

First the state space form for the stationary case—that is, when $d = 0$ and $D = 0$, is explained. A number of alternate state space forms are possible in this case; the one described here is based on Jones (1980). With slight abuse of notation, let $p = p + s * P$ denote the effective autoregressive order, and let $q = q + sQ$ denote the effective moving average order of the model. Similarly, let ϕ be the effective autoregressive polynomial, and let θ be the effective moving average polynomial in the backshift operator with coefficients $\phi_1, \dots, \phi_p$ and $\theta_1, \dots, \theta_q$, obtained by multiplying the respective nonseasonal and seasonal factors. Then, a random sequence ξ_t that follows an $\text{ARMA}(p,q) \times (P,Q)_s$ model with a white noise sequence a_t has a state space form with state vector of size $m = \max(p, q + 1)$. The system matrices are as follows: $\mathbf{Z} = [1 \ 0 \ \dots \ 0]$, and the transition matrix $\mathbf{T}$, in a blocked form, is given by

$$\mathbf{T} = \begin{bmatrix} 0 & I_{m-1} \\ \phi_m \ \dots & \phi_1 \end{bmatrix}$$

where $\phi_i = 0$ if $i > p$ and I_{m-1} is an $(m - 1)$ dimensional identity matrix. The covariance of the state disturbance matrix $\mathbf{Q} = \sigma^2 \psi \psi'$, where σ^2 is the variance of the white noise sequence a_t and the vector $\psi = [\psi_0 \ \dots \ \psi_{m-1}]'$ contains the first m values of the impulse response function—that is, the first m coefficients in the expansion of the ratio θ/ϕ . The covariance matrix of the initial state, $\mathbf{Q}_1$, is computed as

$$\text{vec}(\mathbf{Q}_1) = (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1} \text{vec}(\mathbf{Q})$$

where $\otimes$ denotes the Kronecker product and the *vec* operation on a matrix creates a vector formed by vertically stacking the rows of that matrix.

A number of alternate state space forms are possible in the nonstationary case also. The form used by the CSSM procedure utilizes the state space form for the stationary case as a building block. Suppose that a random sequence ξ_t follows an $\text{ARIMA}(p,d,q) \times (P,D,Q)_s$ model with a white noise sequence a_t . As in the notation for the stationary case, with slight abuse of notation, let $d = d + s * D$ denote the effective differencing order, and let Δ be the effective differencing polynomial in the backshift operator with coefficients $\Delta_1, \dots, \Delta_d$. It can be shown that ξ_t has a state space form with state vector size $m^\dagger = m + d$. In what follows, the system matrices and related quantities in the nonstationary case are described in terms of similar entities in the stationary case. A superscript dagger ($\dagger$) has been added to distinguish the entities from the nonstationary case. $\mathbf{Z}^\dagger = [0 \ 0 \ \dots \ 1 \ \dots \ 0]$ where the only nonzero value, 1, is at the index $m + 1$, and the transition matrix, $\mathbf{T}^\dagger$, in a blocked form, is given by

$$\mathbf{T}^\dagger = \begin{bmatrix} \mathbf{T} & 0 & 0 \\ \mathbf{Z}\mathbf{T} & \Delta_1 \ \dots & \Delta_d \\ 0 & I_{d-1} & 0 \end{bmatrix}$$

The state disturbance matrix $\mathbf{Q}^\dagger$ is given by

$$\mathbf{Q}^\dagger = \begin{bmatrix} \mathbf{Q} & \mathbf{QZ}' & 0 \\ \mathbf{ZQ} & \mathbf{ZQZ}' & 0 \\ 0 & 0 & 0 \end{bmatrix}$$

Finally, the initial state is partially diffuse: the first m elements are nondiffuse and the last d elements are diffuse. The covariance matrix of the first m elements is $\mathbf{Q}_1$.

Trend Models for Irregular Data

A good reference for these models is De Jong and Mazzi (2001). Throughout this section $h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points. The system matrices $\mathbf{T}_t$ and $\mathbf{Q}_t$ that govern these models depend on h_t . However, whenever the notation is unambiguous, the subscript t is omitted.

Polynomial Spline Trend

This model is a general-purpose tool for extracting a smooth trend from the noisy data. The order of the spline governs the order of the local polynomial that defines the spline. The order-1 spline corresponds to Brownian motion (continuous-time random walk), the order-2 spline corresponds to integrated Brownian motion (continuous-time integrated random walk), and the order-3 spline provides a locally quadratic trend; the default order is 1. The dimension of the state underlying this component is the same as the order of the spline. The system matrices for the orders up to 3 are described as follows (in all the cases the initial condition is fully diffuse):

- order-1 spline: $\mathbf{Z} = (1)$, $\mathbf{T} = (1)$, and $\mathbf{Q} = \sigma^2(h)$
- order-2 spline: $\mathbf{Z} = (1 \ 0)$, $\mathbf{T} = (1 \ h, \ 0 \ 1)$, and $\mathbf{Q} = \sigma^2 \left(\frac{h^3}{3} \ \frac{h^2}{2}, \ \frac{h^2}{2} \ h \right)$
- order-3 spline: $\mathbf{Z} = (1 \ 0 \ 0)$, $\mathbf{T} = \left(1 \ h \ \frac{h^2}{2}, 0 \ 1 \ h, 0 \ 0 \ 1 \right)$, and

$$\mathbf{Q}[i, j] = \sigma^2 * \frac{h^{6-i-j+1}}{(6-i-j+1)(3-i)!(3-j)!} \quad 1 \leq i, j \leq 3$$

The system matrices for higher orders are similarly defined (for more information, see De Jong and Mazzi (2001)).

Note that, in addition to providing an estimate of the trend, this methodology can provide estimates of the higher-order derivatives of the trend. If $\boldsymbol{\alpha}$ denotes the k -dimensional subsection that is associated with a polynomial spline of order k , then its j th element ($1 \leq j \leq k$), $\boldsymbol{\alpha}[j]$, corresponds to the derivative of order $(j-1)$ of this polynomial spline. For an example of the estimation of the first derivative of a trend component, see “[Example 14.12: Long-Term Temperature Trends Based on a Multivariate Model](#)” on page 864. For additional information about using these types of trend patterns in data analysis, see Eubank, Huang, and Wang (2003); Kohn, Ansley, and Tharm (1991); Selukar (2015).

Decay and Growth Trends

There are two choices for the decay trend: DECAY and DECAY(OU). Similarly, there are two choices for the growth trend: GROWTH and GROWTH(OU). The “OU” stands for the Ornstein-Uhlenbeck form of these models. The decay trend is a sum of two correlated components: one component is a random walk, and the

other component is a stationary autoregression. In its Ornstein-Uhlenbeck form, the random walk component is replaced by a constant. The growth trend (and its Ornstein-Uhlenbeck variant) has the same form as the decay trend except that the autoregression is nonstationary (in fact, it is explosive). For growth trend models, floating-point errors can result for even moderately long forecast horizons because of the explosive growth in the trend values.

The system matrices for the decay and the growth types in their respective cases are identical, except for the sign of the rate parameter ϕ : $\phi < 0.0$ for the decay type, and $\phi > 0.0$ for the growth type. In addition, the initial conditions for the growth models are fully diffuse; they are only partially diffuse for the decay models. The underlying state vector for all these models is two-dimensional.

The system matrices for the DECAF type are

$$\begin{aligned} \mathbf{Z} &= (1 \ 1) \\ \mathbf{T} &= \text{Diag}(1, \exp(h\phi)) \\ \mathbf{Q} &= \frac{\sigma^2}{\phi^3} (h\phi \ 1 - \exp(h\phi), \ 1 - \exp(h\phi) \ (\exp(2h\phi) - 1)/2) \end{aligned}$$

The initial condition is partially diffuse with $\mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi^3})$. The system matrices for the GROWTH type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

For the DECAF(OU) type, $\mathbf{Z}$ and $\mathbf{T}$ are the same as DECAF, whereas

$$\mathbf{Q} = \text{Diag} \left(0, \sigma^2 \frac{(\exp(2h\phi) - 1)}{2\phi} \right) \text{ and } \mathbf{Q}_1 = \text{Diag}(0, \frac{-\sigma^2}{2\phi})$$

The system matrices for the GROWTH(OU) type are the same (with $\phi > 0.0$), except that the initial condition is fully diffuse; so $\mathbf{Q}_1 = 0$.

Predefined Structural Models

A set of predefined models is available in the CSSM procedure for models called structural models in the time series literature. These predefined models can be used to model trend, seasonal, and cyclical patterns in the univariate and multivariate time series. For the most part, the multivariate models are straightforward generalizations of the corresponding univariate models—for example, the multivariate random walk trend described later in this section generalizes the univariate random walk trend that is described in the section “Random Walk Trend” on page 776. All of these models, with the exception of the continuous-time cycle model, are applicable only to the regular data type. The continuous-time cycle model is applicable to all the data types; however, it is available for the univariate case only.

To specify these models, you must first use the STATE statement with the correct TYPE= option. When you specify the TYPE=option, you do not need to specify other options of the STATE statement (for example, the T option, the COV1 option, and the A1 option). However, you must specify the COV option, which describes the covariance of the disturbance term that drives the state equation. Throughout this section, the symmetric matrix specified by using the COV option is denoted by Σ . For TYPE= LL, an additional matrix, specified by using the SLOPECOV suboption, also plays a role; it is denoted by Σ_{slope} . Subsequently you must specify one or more COMPONENT statements to define the (univariate) components that are based on this state subsection for their inclusion in the MODEL statement. These univariate components exhibit

interesting behavior based on the structure of Σ (and Σ_{slope} , whenever applicable)—for example, imposing rank restrictions on Σ in the multivariate random walk results in these univariate trends moving together. For additional information about these models, see Harvey (1989).

The following example summarizes the steps needed to define a multivariate structural model by using a sequence of STATE and COMPONENT statements. For a full example, see “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803. Suppose that a three-dimensional time series is being studied with response variables y_1 , y_2 , and y_3 . Suppose you want to specify the trivariate structural model

$$y_t = \mu_t + \psi_t + \epsilon_t$$

where $y_t = (y_{1,t}, y_{2,t}, y_{3,t})$ denotes the response series, and μ_t , ψ_t , and ϵ_t denote the trivariate components, trend, cycle, and white noise, respectively. The three components of ϵ_t , the observation noise in the model, are not assumed to be independent. Therefore, you cannot specify them by using three IRREGULAR statements; you must include them in the state specification. The following (incomplete) statements show how to specify this model:

```
state whiteNoise(3)  type=wn ...;
component wn1 = whiteNoise[1];
component wn2 = whiteNoise[2];
component wn3 = whiteNoise[3];

state randomWalk(3)  type=rw ...;
component rw1 = randomWalk[1];
component rw2 = randomWalk[2];
component rw3 = randomWalk[3];

state cycleState(3)  type=cycle ...;
component c1 = cycleState[1];
component c2 = cycleState[2];
component c3 = cycleState[3];

model y1 = rw1 c1 wn1;
model y2 = rw2 c2 wn2;
model y3 = rw3 c3 wn3;
```

The first STATE statement defines `whiteNoise`, a state subsection that is needed for defining a three-dimensional white noise component. In turn, `whiteNoise` is used to define the three univariate white noise components: `wn1`, `wn2`, and `wn3`. The components `wn1`, `wn2`, and `wn3` are correlated—their correlation structure is controlled by the covariance specification of `whiteNoise`. The second set of STATE and COMPONENT statements result in three correlated random walk trend components: `rw1`, `rw2`, and `rw3`. Finally, the last set of STATE and COMPONENT statements result in three correlated cycle components: `c1`, `c2`, and `c3`. In the end, the desired multivariate model is defined by including these (univariate) components in the appropriate MODEL statements.

In the preceding example, it is important to note the relationship between the nominal dimension (denoted by *dim* throughout this section) that is specified in the STATE statement and the actual dimension of the resulting state subsection. Note that the three state subsections, `whiteNoise`, `randomWalk`, and `cycleState`, are defined by using the same *dim* specification: 3. However, the actual dimensions of these state subsections depend on their type; they do not need to equal this specified dimension. Here, `whiteNoise` and `randomWalk` do have the same size, 3, as the specified *dim*. However, the size of `cycleState`, which is of TYPE=CYCLE, is $2 * \text{dim} = 6$. Another important point to note: no matter what the underlying size of the state subsection, the

desired univariate components were obtained by using an identical specification scheme in the COMPONENT statement. This happens because the component specification style that is based on the element operator—[]—in the COMPONENT statement behaves differently when the TYPE= option is used to define the state subsection (for an illustration, see the section “Multivariate Season” on page 783).

The system matrices for all these models are time-invariant, with the exception of the continuous-time cycle model. In this section, α_t denotes the subsection of the overall model state α_t , and T , Q , and A_1 denote the corresponding blocks of the larger system matrices.

For the multivariate cycle system matrices described in the section “Multivariate Cycle” on page 782, the Kronecker product notation is useful: if A is an $m \times n$ matrix and B is a $p \times q$ matrix, then the Kronecker product $A \otimes B$ is an $mp \times nq$ block matrix:

$$A \otimes B = \begin{bmatrix} a_{11}B & \cdots & a_{1n}B \\ \vdots & \ddots & \vdots \\ a_{m1}B & \cdots & a_{mn}B \end{bmatrix}$$

Multivariate White Noise

The STATE statement option **TYPE=WN** specifies white noise of dimension *dim*—that is, a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system matrices is trivial: T is zero, $Q = \Sigma$, and the initial condition is nondiffuse ($Q_1 = \Sigma$ and $A_1 = 0$).

Multivariate white noise is needed to specify the observation equation noise term for the multivariate models for the time series data. Since the state space formulation for the CSSM procedure requires the observation equation noise vector to have the diagonal form, you need to include the noise vector in the state. The noise term for the *i*th response variable is defined by a component that simply picks the *i*th element of this multivariate white noise. For example, the component `wn_i` defined as follows can be used as a noise term in the MODEL statement of the *i*th response variable:

```
state white(dim) type=wn ...;
component wn_3 = white[3];
```

Multivariate Random Walk Trend

The STATE statement option **TYPE=RW** specifies a *dim*-dimensional random walk

$$\alpha_{t+1} = \alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance Σ . The specification of the associated system matrices is trivial: T is a *dim*-dimensional identity matrix, I_{dim} , $Q = \Sigma$, and the initial condition is fully diffuse ($Q_1 = 0$ and $A_1 = I_{dim}$).

The multivariate random walk is a useful trend model for multivariate time series data. The trend term for the *i*th response variable is defined by a component that simply picks the *i*th ($1 \leq i \leq dim$) element of α_t . For example, the component `rw_i` defined as follows can be used as a trend term in the MODEL statement of the *i*th response variable:

```
state randomWalk(3) type=rw ...;
component rw_2 = randomWalk[2];
```

Multivariate Local Linear Trend

The STATE statement option **TYPE=LL** specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional local linear trend. The first dim elements of α_t correspond to the needed multivariate trend, and the subsequent dim elements are needed to capture the slope vector of this trend. α_t can be defined as

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma_{\text{slope}})$ and T is a $2*dim$ -dimensional block matrix $T = (\mathbf{I}_{dim} \ \mathbf{I}_{dim}, \ \mathbf{0} \ \mathbf{I}_{dim})$. The initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*dim}$). This is a multivariate generalization of the univariate local linear trend.

The multivariate local linear trend is a useful trend model for multivariate time series data. The trend term for the i th response variable is defined by a component that simply picks the i th element ($1 \leq i \leq dim$) of α_t . For example, the component `ll_i` defined as follows can be used as a trend term in the MODEL statement of the i th response variable:

```
state localLin(dim) type=ll(slopecov...) ...;
component ll_3 = localLin[3];
```

Multivariate Cycle

The STATE statement option **TYPE=CYCLE** specifies a $(2*dim)$ -dimensional α_t , needed for defining a dim -dimensional cycle. As in the LL case, the first dim elements of α_t correspond to the needed dim -dimensional cycle, and the remaining dim elements contain some auxiliary quantities. The cycle model defined in this subsection requires a regular data type—that is, the CT option is not included. Let ρ denote the damping factor, and let $\lambda = 2\pi/\text{period}$ be the frequency associated with the cycle. The admissible parameter ranges are $0 < \rho \leq 1$ and $\text{period} > 2$, which implies that $0 < \lambda < \pi$. Let $\mathbf{C} = \rho(\cos(\lambda) \ \sin(\lambda), \ -\sin(\lambda) \ \cos(\lambda))$, a 2×2 matrix, and let $\mathbf{T} = \mathbf{C} \otimes \mathbf{I}_{dim}$, a $2 * dim \times 2 * dim$ matrix. With this notation, the transition equation associated with α_t is

$$\alpha_{t+1} = T\alpha_t + \eta_{t+1}$$

where η_t is a sequence of zero mean, independent, $(2 * dim)$ -dimensional Gaussian vectors with covariance $\text{Diag}(\Sigma, \Sigma)$. If $\rho = 1$, the initial condition is fully diffuse ($\mathbf{Q}_1 = 0$ and $\mathbf{A}_1 = \mathbf{I}_{2*dim}$). Otherwise, it is nondiffuse: $\mathbf{Q}_1 = \frac{1}{(1-\rho^2)}\text{Diag}(\Sigma, \Sigma)$ and $\mathbf{A}_1 = 0$.

The multivariate cycle is useful for capturing periodic behavior for multivariate time series data. The cycle term for the i th response variable is defined by a component that simply picks the i th element of α_t . For example, the component `cycle_i` defined as follows can be used as a cycle term in the MODEL statement of the i th response variable:

```
state cycleState(dim) type=cycle ...;
component cycle_2 = cycleState[2];
```

Multivariate Season

The STATE statement option **TYPE=SEASON(LENGTH=s)** specifies a $((s-1)*dim)$ -dimensional α_t , needed for defining a dim -dimensional trigonometric season component with season length s . A (multivariate) trigonometric season component, ζ , is a sum of (multivariate) cycles of different frequencies,

$$\zeta = \sum_{j=1}^{[s/2]} \zeta_j$$

where the constituent cycles ζ_j , called harmonics, have frequencies $\lambda_j = 2\pi j/s$. All the harmonics are assumed to be statistically independent, have the same damping factor $\rho = 1$, and are governed by the disturbances with the same covariance matrix Σ . The number of harmonics, $[s/2]$, equals $s/2$ if s is even and $(s-1)/2$ if it is odd. This means that specifying **TYPE=SEASON(LENGTH=s)** is equivalent to specifying $[s/2]$ cycle specifications with correct frequencies, damping factor $\rho = 1$, and the **COV** option restricted to the same covariance Σ . The resulting α_t is necessarily $((s-1)*dim)$ -dimensional. When the season length s is even, the last harmonic cycle, $\zeta_{s/2}$, has frequency π and requires special attention. It is of dimension dim rather than $2*dim$ because its underlying state equation simplifies to a dim -variate autoregression with autoregression coefficient $-\mathbf{I}_{dim}$. As a result of this discussion, it is clear that the system matrices **T** and **Q** associated with the $((s-1)*dim)$ -dimensional α_t are block-diagonal with the blocks corresponding to the harmonics. The initial condition is fully diffuse.

For all the models discussed so far, the first dim elements of α_t provided the needed (multivariate) component. This is not the case for the (multivariate) season component. Extracting the i th seasonal component from α_t requires accumulating the contributions from the $[s/2]$ harmonics that are associated with this i th seasonal, which are not organized contiguously in α_t . For example, suppose that dim is 2 and the season length s is 4. In this case $[s/2]$ is 2, and the bivariate seasonal component is a sum of two independent bivariate cycles, ζ_1 and ζ_2 . The cycle ζ_1 has frequency $\pi/2$ and its underlying state, say α_t^a , has dimension $2 * dim = 4$. The last harmonic, ζ_2 , has frequency π , and therefore its underlying state, say α_t^b , has dimension 2. The combined state $\alpha_t = (\alpha_t^a, \alpha_t^b)$ has dimension $6 = 4 + 2$. In order to extract the first bivariate seasonal component, you must extract the first components of bivariate cycles ζ_1 and ζ_2 , which in turn implies the first elements of α_t^a and α_t^b , respectively. Thus, obtaining the first bivariate seasonal component requires extracting the first and the fifth elements of the combined state α_t . Similarly, obtaining the second bivariate seasonal component requires extracting the second and the sixth elements of the combined state α_t . All this can be summarized by the dot product expressions

$$\begin{aligned} s_{1t} &= (1 \ 0 \ 0 \ 0 \ 1 \ 0) \alpha_t \\ s_{2t} &= (0 \ 1 \ 0 \ 0 \ 0 \ 1) \alpha_t \end{aligned}$$

where s_{1t} and s_{2t} denote the first and second components, respectively, of the bivariate seasonal component. Note that s_{1t} and s_{2t} are univariate seasonal components, each of season length 4, in their own right. They are correlated components; their correlation structure depends on Σ .

Obtaining the desired components of the multivariate seasonal component is made easy by a special syntax convention of the **COMPONENT** statement. Continuing with the previous example, the following examples illustrate two equivalent ways of obtaining s_{1t} and s_{2t} . The first set of statements explicitly specify the linear combinations needed for defining s_{1t} and s_{2t} :

```
state seasonState(2) type=season(length=4) ...;
component s_1 =( 1 0 0 0 1 0 ) * seasonState;
component s_2 =( 0 1 0 0 0 1 ) * seasonState;
```

The following simpler specification achieves the same result:

```
state seasonState(2) type=season(length=4) ...;
component s_1 = seasonState[1];
component s_2 = seasonState[2];
```

In the latter specification, the meaning of the element operator [] changes if the state in question is defined by using the **TYPE=** option.

Multivariate ARMA

You can specify a state vector that follows a multivariate autoregressive, moving average (VARMA) model by using the STATE statement option **TYPE=VARMA**. The autoregressive and moving average orders can be either 0 or 1 ($0 \leq p \leq 1$ and $0 \leq q \leq 1$)—that is, only VAR(1), MA(1), and VARMA(1,1) models can be specified. The notation and the state space form of the VARMA model described here is taken from Reinsel (1997), which is a good reference for VARMA modeling.

A dim -dimensional vector process ζ_t follows a zero-mean, autoregressive order p , moving average order q (VARMA(p, q)) model if it satisfies the following matrix difference equation:

$$\zeta_t = \sum_{i=1}^p \Phi_i \zeta_{t-i} + \epsilon_t - \sum_{j=1}^q \Theta_j \epsilon_{t-j}$$

Here Φ_i and Θ_j are dim -dimensional square matrices and ϵ_t is a dim -dimensional, Gaussian, white noise sequence with covariance matrix Σ . If autoregressive order p is 0, the term that involves Φ_i is absent; similarly, if the moving average order q is 0, the term that involves Θ_j is absent. Since AR and MA orders can be at most 1, the subscripts of Φ_i and Θ_j can be ignored in this discussion—when applicable, an AR coefficient matrix is denoted by Φ and an MA coefficient matrix is denoted by Θ . The unknown elements of Φ , Θ , and Σ constitute the parameter vector that is associated with a VARMA state. The process ζ_t defined by the VARMA difference equation is stationary and invertible (Reinsel 1997) if and only if the eigenvalues of Φ and Θ are strictly less than 1 in magnitude. By default, the CSSM procedure imposes these stationarity and invertibility restrictions on Φ and Θ . However, you can specify Φ to be an identity matrix, in which case the resulting process is nonstationary.

A VARMA model can be cast into a state space form. The state space form used by the CSSM procedure is described in Reinsel (1997, pp. 52–53). The system matrices for the supported VARMA models are as follows:

- The VAR(1) form is the simplest. In this case, the underlying state α_t is the same as the VAR(1) process ζ_t . Therefore, $T = \Phi$ and $Q_t = \Sigma$.
- Taking Φ equal to the zero matrix if $p = 0$, the VARMA(1,1) and MA(1) cases can be treated together. In this case, the underlying state α_t is $2*dim$ dimensional and the desired VARMA process ζ_t corresponds to its first dim elements. Let $\Psi = \Phi - \Theta$. Then, in the blocked form,

$$T = \begin{bmatrix} 0 & I_{dim} \\ 0 & \Phi \end{bmatrix} \quad \text{and} \quad Q_t = Q = \begin{bmatrix} \Sigma & \Sigma\Psi' \\ \Psi\Sigma & \Psi\Sigma\Psi' \end{bmatrix}$$

Unless Φ is restricted to be identity, the underlying state α_t is stationary and the covariance of the initial condition is computed by

$$\text{vec}(\mathbf{Q}_1) = (\mathbf{I} - \mathbf{T} \otimes \mathbf{T})^{-1} \text{vec}(\mathbf{Q})$$

where $\otimes$ denotes the Kronecker product and the *vec* operation on a matrix creates a vector formed by vertically stacking the rows of that matrix. If Φ is restricted to be identity, the initial condition is fully diffuse.

Continuous-Time Cycle

The STATE statement option **TYPE=CYCLE(CT)** specifies a two-dimensional α_t , needed for defining a univariate continuous time cycle. In this case the nominal dimension, *dim*, must be 1. In particular, Σ becomes one-dimensional, which is denoted by σ^2 . This cycle can be used for any data type. As before, the parameters of the cycle are a damping factor ρ , $0 < \rho \leq 1$, and *period* > 0 . Unlike in the discrete-time cycle described in the section “**Multivariate Cycle**” on page 782, the *period* is not required to be larger than 2. Let $\lambda = 2\pi/\text{period}$, and let $h_t = (\tau_{t+1} - \tau_t)$ denote the difference between successive time points. In this case, the system matrices $\mathbf{T}$ and $\mathbf{Q}$ that govern α_t depend on h_t . They are as follows:

$$\begin{aligned} \mathbf{T} &= \rho^{h_t} \begin{pmatrix} \cos(\lambda h_t) & \sin(\lambda h_t) \\ -\sin(\lambda h_t) & \cos(\lambda h_t) \end{pmatrix} \\ \mathbf{Q} &= \frac{\sigma^2(1 - \rho^{2h_t})}{-2 \ln(\rho)} * \mathbf{I}_2 \quad \text{if } \rho < 1 \\ \mathbf{Q} &= \sigma^2 h_t \mathbf{I}_2 \quad \text{if } \rho = 1 \end{aligned}$$

If $\rho < 1$, the initial condition is nondiffuse: $\mathbf{Q}_1 = \frac{\sigma^2}{-2 \ln(\rho)} \mathbf{I}_2$. For $\rho = 1$, the initial condition is fully diffuse.

The first element of α_t corresponds to the needed cycle, and the second element is an auxiliary quantity. You can define a cycle term based on this state as follows:

```
state cycleState(1) type=cycle(CT) ...;
component cycle = cycleState[1];
```

The CT option must be included in the use of **TYPE=CYCLE**.

Models with Dependent Lags

Many useful time series models relate the present value of a response variable to its own lagged values and, in the multivariate case, the lagged values of other response variables in the model. In the CSSM procedure, you can use the **DEPLAG** statement to specify the terms in the model that involve lagged response variables. These models apply only to the regular data type. This section describes the state space form of such models; for more information, see Harvey (1989, sec. 7.1.1). As an illustration, consider the following model, where the q -dimensional coefficient matrices Φ_1 and Φ_2 are either fully or partially known:

$$\begin{aligned} \mathbf{Y}_t &= \Phi_1 \mathbf{Y}_{t-1} + \Phi_2 \mathbf{Y}_{t-2} + \mathbf{Z}_t \alpha_t + \mathbf{X}_t \beta + \epsilon_t \\ \alpha_{t+1} &= \mathbf{T}_t \alpha_t + \mathbf{W}_{t+1} \gamma + \mathbf{c}_{t+1} + \eta_{t+1} \\ \alpha_1 &= \mathbf{c}_1 + \mathbf{A}_1 \delta + \eta_1 \end{aligned}$$

Except for the presence of the terms that involve lagged response vectors ($\Phi_1 \mathbf{Y}_{t-1}$ and $\Phi_2 \mathbf{Y}_{t-2}$) in the observation equation, the form of this model is the same as the standard state space form that is described in

the section “State Space Model and Notation” on page 760. It turns out that this model can be expressed in the standard state space form by suitably enlarging the latent vectors in the state equation and by appropriately reorganizing the system matrices. The enlarged latent vectors and the corresponding system matrices are distinguished by the presence of dagger ($\dagger$) as a superscript in the following reformulated model,

$$\begin{aligned} \mathbf{Y}_t &= \mathbf{Z}_t^\dagger \boldsymbol{\alpha}_t^\dagger \\ \boldsymbol{\alpha}_{t+1}^\dagger &= \mathbf{T}_t^\dagger \boldsymbol{\alpha}_t^\dagger + \mathbf{W}_{t+1}^\dagger \boldsymbol{\gamma}^\dagger + \mathbf{c}_{t+1}^\dagger + \boldsymbol{\eta}_{t+1}^\dagger \\ \boldsymbol{\alpha}_1^\dagger &= \mathbf{c}_1^\dagger + \mathbf{A}_1^\dagger \boldsymbol{\delta}^\dagger + \boldsymbol{\eta}_1^\dagger \end{aligned}$$

where the following conditions are true (column vectors are displayed horizontally to save space):

- The enlarged state vector ($\boldsymbol{\alpha}_t^\dagger$) is formed by vertically stacking the old state vector ($\boldsymbol{\alpha}_t$), the observation disturbance vector ($\boldsymbol{\epsilon}_t$), and the present and lagged response vectors ($\mathbf{Y}_t$ and $\mathbf{Y}_{t-1}$, respectively). That is, $\boldsymbol{\alpha}_t^\dagger = [\boldsymbol{\alpha}_t \ \boldsymbol{\epsilon}_t \ \mathbf{Y}_t \ \mathbf{Y}_{t-1}]$. Because $\boldsymbol{\alpha}_t$ is m -dimensional and $\boldsymbol{\epsilon}_t$, $\mathbf{Y}_t$, and $\mathbf{Y}_{t-1}$ are q -dimensional, the dimension of $\boldsymbol{\alpha}_t^\dagger$ is $m^\dagger = (m + 3 * q)$.
- The new state regression vector ($\boldsymbol{\gamma}^\dagger$) is formed by vertically stacking the old state regression vector ($\boldsymbol{\gamma}$) and the observation equation regression vector ($\boldsymbol{\beta}$). That is, $\boldsymbol{\gamma}^\dagger = [\boldsymbol{\gamma} \ \boldsymbol{\beta}]$.
- The enlarged disturbance vector ($\boldsymbol{\eta}_t^\dagger$) is formed by vertically stacking the old state disturbance vector ($\boldsymbol{\eta}_t$), the observation disturbance vector ($\boldsymbol{\epsilon}_t$), the vector sum ($\mathbf{Z}_t \boldsymbol{\eta}_t + \boldsymbol{\epsilon}_t$), and filling the rest of the vector with zeros. That is, $\boldsymbol{\eta}_t^\dagger = [\boldsymbol{\eta}_t \ \boldsymbol{\epsilon}_t \ (\mathbf{Z}_t \boldsymbol{\eta}_t + \boldsymbol{\epsilon}_t) \ \mathbf{0}]$.
- The deterministic vector $\mathbf{c}_{t+1}^\dagger = [\mathbf{c}_{t+1} \ \mathbf{0} \ \mathbf{Z}_{t+1} \mathbf{c}_{t+1} \ \mathbf{0}]$.
- The last $2q$ elements of the initial state vector ($\boldsymbol{\alpha}_1^\dagger$), which correspond to $\mathbf{Y}_1$, and $\mathbf{Y}_0$, are taken to be diffuse (which means that the diffuse vector $\boldsymbol{\delta}^\dagger$ has $2q$ additional elements compared to $\boldsymbol{\delta}$).

The new system matrices can be described in blockwise form in terms of the old system matrices as follows:

- The $q \times (m + 3 * q)$ -dimensional $\mathbf{Z}_t^\dagger = [\mathbf{0} \ \mathbf{0} \ \mathbf{I} \ \mathbf{0}]$, where $\mathbf{0}$ is either a $q \times m$ -dimensional or $q \times q$ -dimensional matrix of zeros and $\mathbf{I}$ is a q -dimensional identity matrix.
- The $m^\dagger \times m^\dagger$ matrices $\mathbf{T}_t^\dagger$ (transition matrix) and $\mathbf{Q}_t^\dagger$ (covariance of $\boldsymbol{\eta}_{t+1}^\dagger$) are

$$\mathbf{T}_t^\dagger = \begin{bmatrix} \mathbf{T}_t & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \\ \mathbf{Z}_{t+1} \mathbf{T}_t & \mathbf{0} & \boldsymbol{\Phi}_1 & \boldsymbol{\Phi}_2 \\ \mathbf{0} & \mathbf{0} & \mathbf{I} & \mathbf{0} \end{bmatrix} \quad \text{and} \quad \mathbf{Q}_t^\dagger = \begin{bmatrix} \mathbf{Q}_t & \mathbf{0} & \mathbf{Q}_t \mathbf{Z}_{t+1}' & \mathbf{0} \\ \mathbf{0} & \boldsymbol{\Sigma}_{t+1} & \boldsymbol{\Sigma}_{t+1} & \mathbf{0} \\ \mathbf{Z}_{t+1} \mathbf{Q}_t & \boldsymbol{\Sigma}_{t+1} & (\mathbf{Z}_{t+1} \mathbf{Q}_t \mathbf{Z}_{t+1}' + \boldsymbol{\Sigma}_{t+1}) & \mathbf{0} \\ \mathbf{0} & \mathbf{0} & \mathbf{0} & \mathbf{0} \end{bmatrix}$$

where $\boldsymbol{\Sigma}_t$ denotes the covariance matrix (which is diagonal by design) of the observation error vector $\boldsymbol{\epsilon}_t$. Recall that the system matrices in the transition equation can depend on both t and $t + 1$ even if the subscripts of $\mathbf{T}$ and $\mathbf{Q}$ show dependence on t alone.

- The $m^\dagger \times (k + g)$ matrix $\mathbf{W}_t^\dagger$ is

$$\mathbf{W}_{t+1}^\dagger = \begin{bmatrix} \mathbf{W}_{t+1} & \mathbf{0} \\ \mathbf{0} & \mathbf{0} \\ \mathbf{Z}_{t+1} \mathbf{W}_{t+1} & \mathbf{X}_{t+1} \\ \mathbf{0} & \mathbf{0} \end{bmatrix}$$

This state space form can be easily extended to account for higher-order lags.

Models that contain dependent lag terms must be used with care. Because the CSSM procedure does not impose any special constraints on the lag coefficients (the elements of coefficient matrices Φ_1 , Φ_2 , and so on), the resulting models can often be explosive. For an example of a model with lagged response variables, see “[Example 14.13: Bivariate Model for Sales of Mink and Muskrat Furs](#)” on page 871.

PROC CSSM and PROC UCM (see Chapter 30, “[UCM Procedure](#)”) handle models that contain dependent lags in essentially the same way. However, there is one difference: if the model parameter vector contains unknown lag parameters, PROC UCM parameters are estimated by optimizing the nondiffuse part of the likelihood, whereas PROC CSSM continues to use the full diffuse likelihood for parameter estimation.

Simulation Smoothing

Like the Kalman filter and Kalman smoother algorithms (DKFS) that are described in the section “[Filtering, Smoothing, Likelihood, and Structural Break Detection](#)” on page 767, the simulation smoother algorithm is an important tool in SSM-based data analysis. The simulation smoother in the CSSM procedure is loosely based on the algorithm described in Durbin and Koopman (2012, chap. 4, sec. 9). Recall that the smoothing phase of DKFS provides the mean and the covariance of a latent state at any time point t , $E(\alpha_t|Y)$ and $\text{Cov}(\alpha_t|Y)$, conditional on the full observed sample Y (see the section “[Smoothing Phase](#)” on page 772). However, the DKFS does not provide information about the joint conditional distribution at different time points; for example, it does not provide the conditional covariance $\text{Cov}(\alpha_{t_1}, \alpha_{t_2}|Y)$ at two distinct time points, t_1 and t_2 . The simulation smoother provides a solution to this problem. You can use the simulation smoother to generate a random draw, $(\tilde{\beta}, \tilde{\gamma}, \tilde{\alpha}_1, \dots, \tilde{\alpha}_n)$, from the joint conditional distribution of $(\beta, \gamma, \alpha_1, \dots, \alpha_n)$, given the sample Y . By making a sufficiently large number of draws from the joint conditional distribution, you can obtain the sampling distribution of arbitrarily complex functions of the conditional estimates of $(\beta, \gamma, \alpha_1, \dots, \alpha_n)$.

In PROC CSSM, the simulation smoothing process is divided into two steps. In the first step, you save the fitted model to an output BLOB table by using the `OUTMODEL=` option in the `SIMSMOOTH` statement as follows:

```
proc cssm data=data-table;
  id ...;
  /*---model specification---*/
  ...;
  simsmooth outmodel=blob-table;
run;
```

In the second step, you use the input data table that was used for model fitting and the BLOB table that was saved from the first step to generate the desired number of simulations from the conditional distribution as follows:

```
proc cssm data=data-table;
  simsmooth inmodel=blob-table nsim=integer seed=integer
    outstate=output-table outcomp=output-table
    outpred=output-table;
run;
```

In this second step, because the loaded `INMODEL=` option BLOB table already contains the full model specification, you do not need to specify the statements that describe the model. Moreover, you can repeat

this second step as many times as needed to get the desired simulation output. The primary output of the simulation smoother is the desired number of random draws of the latent states. You can save this output for later use in a table that you specify in the **OUTSTATE=** option. Depending on the size of the underlying state vector, the number of distinct time points in the input data table, and the specified number of random draws, the **OUTSTATE=** table can get quite large. In many practical situations, you might not need to save this level of detail. In fact, you might be interested only in the simulations of the predictions of the missing response values or of the components in the model. Because they are known linear combinations of the latent states, you can easily obtain them as a by-product of the state simulation output. You can save the simulations of the predictions of the missing response values in a table by using the **OUTPRED=** option, and you can save the simulations of the components in the model by using the **OUTCOMP=** option. The **OUTPRED=** and **OUTCOMP=** tables are usually much smaller than the **OUTSTATE=** table. For more information about the contents of these tables, see the section “Output Tables Associated with Simulation Smoothing” on page 788. For an application of simulation smoothing, see “Example 14.21: Simulation-Smoothing-Based Sampling Distribution of the Sum of Forecasts” on page 901.

Output Tables Associated with Simulation Smoothing

The simulation smoothing process in PROC CSSM enables you to organize the simulation output in three tables: the **OUTSTATE=** table, which contains the simulations of the latent states; the **OUTCOMP=** table, which contains the simulations of the model components; and the **OUTPRED=** table, which contains the simulations of the predictions of the missing response variable values. All these tables share three columns: the **BY** statement variables column; the **SEED** variable column, which contains the seed value that is associated with the random draw; and the **ID** statement variable column. The values of the **SEED** variable range from *integer* to *integer+nsim-1*, where *integer* is the value of the **SEED=** option and *nsim* is the number of draws that you specify in the **NSIM=** option. Additionally, the mean of the sampling distribution for each simulated quantity is also included for reference, and the **SEED** value that is assigned to it is always -1. The mean of the sampling distribution is computed in the smoothing phase (for more information, see the section “Smoothing Phase” on page 772). The other columns in these tables depend on the specified model. The details are presented in the following sections.

OUTCOMP= Table

The **OUTCOMP=** table has the following columns:

- **BY** variables
- **SEED**
- **ID** variable
- **OBSINDEX** variable, if present
- **Smoothed_compName**, where *compName* is a component that is specified in either a **COMPONENT**, **EVAL**, **IRREGULAR**, or **TREND** statement

OUTPRED= Table

The OUTPRED= table has the following columns:

- BY variables
- SEED
- ID variable
- OBSINDEX variable, if present
- SimSmooth_response, where response is a response variable

OUTSTATE= Table

The OUTSTATE= table has the following columns:

- BY variables
- SEED
- ID variable
- stateName_STATE_i, which denotes the *i*th element of state named stateName
- stateName_STATE_REG_i, which denotes the *i*th element of the state regression vector (if present) for the state named stateName
- trendName_TREND_STATE_i, which denotes the *i*th element of the state that underlies the trend named trendName
- irregularName_STATE_i, which denotes the *i*th element of the state that underlies an irregular component, named irregularName, if it is part of the model state vector. In some cases, such as when a model contains a dependent lag term, the irregular component is part of the model state vector.
- deplagName_STATE_i, which denotes the *i*th element of the state that underlies a dependent lag term named deplagName
- response_COEFF_predVar, which denotes the regression coefficient of a predictor variable, predVar, that is specified in the model for a response variable named response

Temporal Aggregation and Temporal Distribution

The response variables in time series analysis are often classified as either stock variables or flow variables. Stock variables, such as interest rates or temperatures, are measured at a particular point in time. Flow variables, such as monthly income or weekly sales, are defined with respect to an interval of time. Flow variables have the property that they remain meaningful under the operations of temporal aggregation and temporal distribution—for example, aggregation of daily sales to weekly sales and distribution (or disaggregation) of weekly sales to daily sales are quite natural, whereas the same cannot be said of temperature readings. This section explains how you can use the CSSM procedure to do model-based temporal aggregation and distribution of flow variables. State space models are often used to carry out model-based temporal aggregation and distribution. Two properties of state space models make them particularly suitable for this purpose:

- If a variable is modeled by a state space model at a particular time interval, its aggregated form—for example, daily to monthly—also follows a state space model. Moreover, the state space forms of these two models have a simple relationship.
- State space models can easily handle missing response values.

The discussion in this section, which is based on Harvey (1989, chap. 6, sec. 3), is limited to regular data types—that is, the data must be either univariate or multivariate time series.

Temporal Distribution

For the sake of simplicity, consider a simple case of distributing weekly observations of a flow variable, y , at a daily interval. Even though the values of y are observed weekly (suppose they are recorded each Sunday), in this case it is necessary to treat the observations $y_t, t \geq 1$, as a daily time series such that y_t equals the weekly total when t corresponds to the end of the week (Sunday), and y_t is missing on other days of the week. In addition, suppose that $y_t^\dagger$ denotes the unobserved time series of daily values of y . In other words, if t corresponds to a Sunday, then

$$y_t = \sum_{s=t-6}^t y_s^\dagger$$

Suppose that the unobserved daily series $y_t^\dagger$ can be modeled by a state space model. For example, suppose the model for $y_t^\dagger$ is

$$\begin{aligned} y_t^\dagger &= \mathbf{Z}_t \boldsymbol{\alpha}_t + \epsilon_t \\ \boldsymbol{\alpha}_{t+1} &= \mathbf{T}_t \boldsymbol{\alpha}_t + \boldsymbol{\eta}_{t+1} \end{aligned}$$

Then it is easy to see that the aggregated series y_t follows a state space model of the form

$$\begin{aligned} y_t &= \mathbf{Z}_t^\dagger \boldsymbol{\alpha}_t^\dagger \\ \boldsymbol{\alpha}_{t+1}^\dagger &= \mathbf{T}_t^\dagger \boldsymbol{\alpha}_t^\dagger + \boldsymbol{\eta}_{t+1}^\dagger \end{aligned}$$

where the following are true (both the row and column vectors are displayed horizontally to save space):

- The new state vector ($\alpha_t^\dagger$) is formed by augmenting the old state vector (α_t) with a latent variable, y_t^f . That is, $\alpha_t^\dagger = [\alpha_t \ y_t^f]$. In fact, y_t^f represents the within-week running total of $y_t^\dagger$, so that when t corresponds to a Sunday, $y_t^f = y_t$.
- The new transition matrix $T_t^\dagger$ is

$$T_t^\dagger = \begin{bmatrix} T_t & 0 \\ Z_{t+1} T_t & \psi_{t+1} \end{bmatrix}$$

where ψ_t is a dummy variable that equals 1 when t is not the start of the week (not Monday) and equals 0 when t is the start of the week (Monday).

- The new disturbance vector ($\eta_t^\dagger$) is formed by augmenting the old disturbance vector (η_t) by $(Z_t \eta_t + \epsilon_t)$. That is, $\eta_t^\dagger = [\eta_t \ Z_t \eta_t + \epsilon_t]$.
- The new design matrix for the state effect ($Z_t^\dagger$) is $Z_t^\dagger = [0 \ 1]$, where 0 is a zero vector of the same size as the old state vector α_t .

This shows that you can do model-based distribution of y values by carrying out the following steps:

- 1 Organize the y values as a daily time series.
- 2 Define a dummy variable, `startWeek`, that flags the start of the week—that is, `startWeek` is 1 when the day is Monday and 0 otherwise. Note that $\psi_t = 1 - \text{startWeek}_t$.
- 3 Specify a suitable state space model for the unobserved daily series $y_t^\dagger$. This specification in turn implies a state space model specification for y .
- 4 Carry out the analysis—model fitting, component estimation, and forecasting—of y in the usual fashion by using this implied model specification.
- 5 The smoothed values of y from the previous step provide the estimates of y_t^f . In addition, the estimates of $y_t^\dagger$ can be obtained as the smoothed estimates of appropriate linear combination of the elements of α_t and ϵ_t .

The CSSM procedure enables you to carry out the key steps—Step 3 to Step 5—in this process quite easily. The usual model specification syntax that uses the `STATE`, `COMPONENT`, and `TREND` statements to define the terms in a `MODEL` statement is used to define a model for the unobserved daily series $y_t^\dagger$ (the first part of Step 3). Then, the use of the `DISTRIBUTE(START=startWeek)` option in the `MODEL` statement causes the CSSM procedure to use the implied model to analyze the observed y values. As a brief illustration, suppose that a data set `Test` contains two variables: `date`, a SAS date variable that indexes the daily observations, and `y`, the values of the weekly variable arranged as a daily series. Then the following PROC CSSM statements show you how to distribute y at the daily interval:

```
proc cssm data=mylib.test;
  id date interval=day;
  startWeek = (weekday(date) = 2); /* indicator of Monday */
  state ...;
  comp term1 = ...;
  ...;
```

```

state noise(1) type=wn ...;
comp wnoise = noise[1];
model y = term1 term2 ... wnoise / distribute(start=startWeek);
/* daily_Y = sum of all terms in the MODEL statement */
eval daily_Y = term1 + term2 + ...+ wnoise;
output out=...;
run;

```

Here are a few comments about this program:

- The terms in the MODEL statement correspond to the observation equation for the unobserved daily series $y_t^\dagger$. However, the DISTRIBUTE(START=*startWeek*) option causes the CSSM procedure to use the implied model (with the augmented state vector) to analyze y —the weekly variable arranged as a daily series.
- Because *wnoise*—the white noise term (ϵ_t) in the observation equation of $y_t^\dagger$ —is subsequently to be used in an EVAL statement, this program specifies it by using the STATE statement rather than by using the IRREGULAR statement.
- Because *daily_Y* (the component specified in the EVAL statement) is the sum of all the terms in the MODEL statement, it corresponds to the unobserved daily series $y_t^\dagger$. Therefore, the smoothed estimate of *daily_Y* (*smoothed_daily_Y*) provides the needed distribution of y at the daily interval.

In this release of the CSSM procedure, the last element of the augmented state vector, y^f , is always initialized with diffuse distribution. A more flexible specification of the initial distribution of y^f might become possible in a future release.

To keep the explanation simple, the preceding discussion was confined to a single response variable. In fact, you can use the CSSM procedure for temporal distribution in more general settings—for example, you can consider temporal distribution of one or more flow variables in a multivariate model that includes one or more response variables of stock type, one or more response variables of flow type, and one or more explanatory variables. An illustration of such modeling is shown in “[Example 14.16: Estimating Monthly GDP by Temporal Distribution](#)” on page 884. The modeling of a response variable as a temporal aggregate of some unobserved latent variable is also needed in a process known as benchmarking; see Durbin and Koopman (2012, chap. 3, sec. 10.2) and Pelagatti (2015, chap. 9, sec. 2). You can use the CSSM procedure in such benchmarking situations as well.

NOTE: Model specification in the temporal distribution setting requires some care. The model for the lower-frequency observed series, y_t , is based on the model specified for the unobserved higher-frequency series $y_t^\dagger$. Because aggregation from higher frequency to lower frequency involves loss of information, an otherwise identifiable model for $y_t^\dagger$ can lead to unidentifiable model for y_t .

Temporal Aggregation

Temporal aggregation is the reverse of temporal distribution. In this case, the observations are available on a finer time scale, and you are interested in estimating the aggregated values on some coarser time scale—for example, estimating weekly totals from daily data. Of course, the aggregation is trivial in the historical region where the observations on the finer scale are known—in fact, in this case the estimation of the aggregate values is done with no estimation error. However, when the aggregate values are to be estimated in the region where the observations on the finer scale are missing—for example, in the forecast

region—the problem becomes nontrivial. It is easier to explain the situation by using a simple example. Suppose y_t , $1 \leq t \leq 100$, denote the daily observations of a response variable, y . Let wy_t , $t \geq 1$, denote the within-week daily running totals—that is, wy_t represents the total of y values up to the day t in the week that contains the day t . Clearly, given the daily values y_t , $1 \leq t \leq 100$, the aggregate values wy_t , $1 \leq t \leq 100$, are fully known. The question is, assuming that y follows a state space model, how do you estimate and obtain appropriate confidence intervals for wy_t in the forecast region ($t = 101, 102, \dots$)? In this section you have already seen that when a variable is modeled by a state space model at a particular time interval, its aggregated form also follows a state space model. The AGGREGATE(START=) option in the MODEL statement of the CSSM procedure enables you to perform temporal aggregation for a response variable. An illustration of such aggregation is shown in “[Example 14.17: Temporal Aggregation-Based Triannual Nile River Level](#)” on page 889.

Covariance Parameterization

The covariance matrices specified by the COV and COV1 options in the STATE statement must be positive semidefinite. When these matrices are of general form and are not user-specified, they are internally parameterized by their Cholesky root. Suppose that Σ , an $m \times m$ positive semidefinite matrix of rank r , is such a covariance matrix. Then, Σ can always be written as

$$\Sigma = RR'$$

where the (generalized) Cholesky root, R , is an $m \times r$ lower triangular matrix with nonnegative diagonal elements (that is, $R[i, j] = 0$ if $j > i$ and $R[i, i] \geq 0$, $1 \leq i \leq r$). The CSSM procedure parameterizes Σ by the elements of its Cholesky root, which adds $r * (r + 1)/2 + r * (m - r)$ elements to the parameter vector θ .

Missing Values

For a variety of reasons the data might contain missing response and predictor values. Before starting the analysis of a particular BY group, CSSM procedure makes an internal copy of the data. The actual analysis is done by using this copy. The data in the copy are first examined for missing values in the response, predictor, and the ID variables. No missing values are permitted in the ID variable (if it is specified). If all the missing values are associated with only the response variables, then the internal copy of the data is not altered. However, if any of the predictors in the observation equation—the elements of $\mathbf{X}$ matrix—are found to contain missing values, the internal copy of the data is altered as follows: any missing predictor value is replaced by 0, and the response values that are dependent on that predictor in the corresponding row are set to missing. These missing response values are called the *induced missing values*. The reported analysis is based on the (possibly altered) internal copy of the BY group.

Missing values are not permitted in any of the other system matrices that define the state space model. In particular, missing values are not permitted in $\mathbf{Z}$, $\mathbf{T}$, $\mathbf{W}$, and $\mathbf{Q}$ matrices. In some cases the elements of these matrices depend on the data values. In such cases, care must be taken to ensure that these data values are not missing.

Scoring with State Space Models

Evaluating a previously fitted model at some new predictor setting is often called scoring. For example, a bank might score a new loan application by applying a rule that is based on a previously fitted logistic regression model. Similarly, you might want to use state space models for scoring. However, because of the sequential nature of the observation process, it is important to realize that the scoring process for state space models is inherently different from the scoring process for models that are based on independent observations, such as simple linear regression or logistic regression. Think of a sequential data process as a streaming movie, which you can pause and resume playing. Watching the movie for some time and learning about the main characters and their relationships to each other is akin to fitting a model to the initial portion of a sequential data stream. After you have learned something about the movie, you can make educated guesses about the subsequent plotline. You can also imagine different ways the movie could play out, while still being consistent with the story thus far. For sequential data, this process of forecasting and what-if analysis, based on the fitted model and ever-increasing history, is called scoring. To explain the scoring features of the CSSM procedure, it is useful to define the following notation, which is based on the section “[State Space Model and Notation](#)” on page 760:

- $(\{Y_t, X_t, W_t\}, t = 1, 2, \dots)$ denote sequential observations on the response variables Y and, optionally, the predictor variables X and W .
- For time points $t_1 \leq t_2$, let $D_{t_1:t_2}$ denote the data between t_1 and t_2 ; that is, $D_{t_1:t_2} = (\{Y_t, X_t, W_t\}, t_1 \leq t \leq t_2)$. With this notation, it is easy to describe a streaming data process in which data arrive sequentially in data packets, possibly of varying lengths. For example, the data packets $D_{1:100}, D_{101:110}, D_{111:112}, \dots$ denote the data that are associated with the first 100 time indices, the data between time indices 101 and 110, the data between time indices 111 and 112, and so on. When there can be multiple measurements that use the same time index, such as in the case of panel data, the ending time index of one data packet can be the same as the starting time index of the next data packet.
- α_t denotes the state vector at time index t , θ denotes the parameter vector, δ denotes the diffuse vector in the initial condition, and β and γ denote the regression vectors that are associated with the observation equation and state equation, respectively.

Armed with this notation, you can understand the main activities of scoring with a state space model, which are explained in the following sections.

Initial Score-Store Creation

After you fit a state space model by using a sufficiently long series of data and you determine that the model is satisfactory, it is ready to be used for scoring. The first step in this process is the creation of a score store. You can use the SCORE statement to create the initial score store, such as `mylib.inscore`, by fitting the model to a suitable series of input data $D_{1:T}$ (`score out=mylib.inscore;`). From this stage forward, the fitted model is assumed to hold for all future time points ($t \geq T$). In particular, the estimated parameter vector, $\hat{\theta}$, is treated as the true and known parameter vector in all subsequent steps. The score store `mylib.inscore` stores the following information:

- the model specification and the estimated parameter vector, $\hat{\theta}$. As part of the model specification, the structural break detection settings in the [STATE](#) and [TREND](#) statements are also stored. Similarly, the

settings of the BREAK and AO options in the **OUTPUT** statement are also saved. If necessary, the options in the **OUTPUT** statement can be modified in later scoring calls.

- $\tilde{\alpha}_T, \tilde{\delta}_T, \tilde{\beta}_T, \tilde{\gamma}_T$, and their covariances, which denote the full-sample (smoothed) estimates of these quantities on the basis of the data $\mathbf{D}_{1:T}$ (for more information, see the section “[Smoothing Phase](#)” on page 772).
- If the score store is created using **OUT(k)=** syntax (**score out (k)=mylib.inscore;**), then $\tilde{\alpha}_{T-k}, \tilde{\delta}_{T-k}, \tilde{\beta}_{T-k}, \tilde{\gamma}_{T-k}$, and their covariances are stored; these are full-sample estimates of these quantities based on the data $\mathbf{D}_{1:(T-k)}$. In this case, the data rows in $\mathbf{D}_{(T-k):T}$ are also stored.

Because of the Markovian property of state space models, the information that the score store contains is sufficient for you to forecast subsequent observations of the process, without having access to its past history.

Incorporating New Information

After you create an initial score store, such as `mylib.inscore`, the scoring process no longer needs the past data ($\mathbf{D}_{1:T}$) that you used to create it. However, as time passes and a data packet, $\mathbf{D}_{(T+1):(T+p)}$, arrives containing new information content, you need to create an updated score store, such as `mylib.outscore`, that incorporates the new information. Because they use the latest information, of course the forecasts for time points after $T + p$ that are based on `mylib.outscore` are better than the forecasts that are based on the old score store, `mylib.inscore`. In PROC CSSM, you can create the updated score store by using the data packet that contains new information ($\mathbf{D}_{(T+1):(T+p)}$) as the input data table and by using the **SCORE** statement with both the **IN=** and **OUT=** options as follows:

```
score in=mylib.inscore out=mylib.outscore;
```

After this, you can discard the old score store, `mylib.inscore`. The new score store, `mylib.outscore`, becomes the score store that is based on the full history up to time $T + p$ ($\mathbf{D}_{1:(T+p)}$). If you created the initial score store by using **OUT(k)=** syntax, the updated score store also stores the data rows in $\mathbf{D}_{(T+p-k):(T+p)}$. You can repeat this score-store updating process again and again as newer information arrives.

What-If Analysis and Process Control

Suppose that a score-store, such as `mylib.inscore`, contains context information based on the data up to time T ($\mathbf{D}_{1:T}$), and suppose you are interested in predicting and/or interpolating the response sequence for the next p time points. You can easily accomplish this in PROC CSSM by using a suitable data packet $\mathbf{D}_{(T+1):(T+p)}$ (or $\mathbf{D}_{T:(T+p)}$ when multiple observations can share the same time index) as the input data table and by using `mylib.inscore` as the input score store in the **SCORE** statement (**score in=mylib.inscore;**). This is called the scoring of data in $\mathbf{D}_{(T+1):(T+p)}$. Because the missing values in the response variables are an indication to PROC CSSM to compute model-based predictions/interpolations, you must set the values of **Y** to missing in appropriate rows of $\mathbf{D}_{(T+1):(T+p)}$ (of course, you must provide appropriate nonmissing values for the predictor variables **X** and **W**).

In what-if analysis, you are interested in predicting the future course of response values for different settings of the predictors **X** and **W**. You can achieve this by repeatedly scoring $\mathbf{D}_{(T+1):(T+p)}$ for different settings of **X** and **W**, while keeping the input score-store the same. See “[Example 14.19: Scenario Analysis Using Scoring](#)” on page 894 for an illustration of this type of what-if analysis.

In process control, the goal is to find suitable predictor settings so that the future response values are close to some desirable levels. In an informal, quick-and-dirty approach, you can do this by repeatedly scoring $\mathbf{D}_{(T+1):(T+p)}$ with different trial values of predictors. In a formal approach, you can use the scoring functionality to define a suitable objective function, which you can optimize by using sophisticated optimization methods to find the optimal predictor settings.

Monitoring of Streaming Data

In many fields, such as industrial process control, monitoring of atmospheric pollutant levels, and so on, a sequential data stream is monitored continuously. The goal is to flag unexpected changes in the normal behavior of the process as soon as possible. Scoring with state space models can be quite useful in these situations. See “[Example 14.20: Monitoring Streaming Data Using Scoring](#)” on page 897 for an illustration of how to use SSM-based scoring to detect level shift in a quarterly series of traffic accident data from the United Kingdom. The following list describes the usual steps in an SSM-based work flow in monitoring cases such as these:

- Find a good model for the normal behavior of the process that is being monitored.
- Create an initial score-store by using a suitably long series of data, $\mathbf{D}_{1:T}$. At creation time, use the $\text{OUT}(k)=$ form with a suitable data window length k , and set the desired structural break detection settings, such as the CHECKBREAK and MAXSHOCK options in the appropriate statements.
- After the initial score-store creation, the process monitoring starts as the new data packets $\mathbf{D}_{(T+1):(T+p)}$, $\mathbf{D}_{(T+p+1):(T+2p)}$, $\dots$ arrive and are scored in succession.
- Each time a new data packet arrives, it is scored, and an updated score store is created that becomes the input score store for processing the next data packet.
- As seen in “[Example 14.20: Monitoring Streaming Data Using Scoring](#)” on page 897, a structural break that happens at a particular time point to be confirmed as a structural break often requires several subsequent observations to be scored. You must make an appropriate choice of k at the time of score-store creation to ensure that a sufficient number of past data rows are retained for detecting structural breaks.
- If a structural break is confirmed at a time point, you can take the following types of action:
 - Flag the structural break, and continue the process monitoring without any further action.
 - Correct the model to take into account the structural break, and continue monitoring.
 - Pause the process, address the causes of the break, and resume monitoring (possibly after modifying the model and refitting).

Computational Issues

A Well-Behaved Model

The model defined by the state space model equations (see the section “[State Space Model and Notation](#)” on page 760) is very general. This generality is quite useful because it encompasses a wide variety of data generation processes. On the other hand, it also makes it easy to specify overly complex and numerically unstable models. If a suitable model is not already known and you are in the early phases of modeling, it is important to start with models that are relatively simple and well-behaved from the numerical standpoint. From the numerical and statistical considerations, two aspects of model formulation are particularly important: identifiability and numerical stability. A model is identifiable if the observed data has a distinct probability distribution for each admissible parameter vector. Unless proper care is taken, it is easy to specify an unidentifiable state space model. Similarly, predictions according to some types of state space models can display explosive growth or wild oscillations. This behavior is primarily governed by the transition matrix $\mathbf{T}$ (or $\mathbf{T}_t$ in the time-varying case). Unidentifiable models can run into difficulties during parameter estimation, and explosive growth (and wild oscillation) causes numerical problems associated with finite-precision arithmetic. Unfortunately, no simple identifiability check is available for a general state space model, and it is difficult to decide at the outset whether a specified model might suffer from numerical instability. For a discussion of identifiability issues, see Harvey (1989, chap. 4, sec. 4). For a discussion of the stability properties of time-invariant state space models, see Harvey (1989, chap. 3, sec. 3). The following guidelines are likely to result in models that are identifiable and numerically stable:

- Build models by composing submodels that are known to be well-behaved. The predefined models provided by the CSSM procedure are good submodel candidates (see the sections “[Predefined Trend Models](#)” on page 776 and “[Predefined Structural Models](#)” on page 779).
- Pay careful attention to the way the variety of system matrices are defined. The behavior of their elements, as functions of model parameters and other variables, must be well-understood. If these elements are defined by using DATA steps, you can validate their behavior by running these DATA steps outside of the CSSM procedure. In particular, note the following:
 - The transition matrix $\mathbf{T}$ (or $\mathbf{T}_t$ in the time-varying case) determines the explosiveness characteristics of the model; it must be well-behaved for all parameters.
 - The disturbance covariances $\mathbf{Q}_t$ must be positive semidefinite for all parameters.
 - If the system matrices in the state equation, such as the transition matrix $\mathbf{T}_t$ or the disturbance covariance $\mathbf{Q}_t$, are time-varying and the data contain replicate observations (observations with the same ID value), check that the elements of these matrices do not vary during replicate observations. This follows from the fact that the underlying state does not vary during replications (see the state equation in the section “[State Space Model and Notation](#)” on page 760 and the section “[Types of Sequence Data](#)” on page 762).

Convergence Problems

As explained in the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769, the model parameters are estimated by nonlinear optimization of the likelihood. This process is not guaranteed to succeed. For some data sets, the optimization algorithm can fail to converge. Nonconvergence can result from a number of causes, including flat or ridged likelihood surfaces and ill-conditioned data. It is also possible for the algorithm to converge to a point that is not the global optimum of the likelihood.

If you experience convergence problems, consider the following:

- Data that are extremely large or extremely small can adversely affect results because of the internal tolerances used during the filtering steps of the likelihood calculation. Rescaling the data can improve stability.
- Whenever possible, parameterize the disturbance variances in the model on the exponential scale. For illustrations of parameterizing disturbance variances in this manner, see “[Example 14.12: Long-Term Temperature Trends Based on a Multivariate Model](#)” on page 864 and “[Example 14.14: A Factor Model for Now-Casting the US Economy](#)” on page 876.
- Examine your model for redundancies in the included components and regressors. The components or regressors that are nearly collinear to each other can cause the optimization process to become unstable.
- Lack of convergence can indicate model misspecification such as unidentifiable model or a violation of the normality assumption.

Computer Resource Requirements

The computing resources required for the CSSM procedure depend on several factors. The memory requirement for the procedure is largely dependent on the number of observations to be processed and the size of the state vector underlying the specified model. If n denotes the sample size and m denotes the size of the state vector, the memory requirement for the smoothing phase of the Kalman filter is of the order of $6 \times 8 \times n \times m^2$ bytes, ignoring the lower-order terms. If the smoothed component estimates are not needed, then the memory requirement is of the order of $6 \times 8 \times (m^2 + n)$ bytes. Besides m and n , the computing time for the parameter estimation depends on the size of the parameter vector θ and how many likelihood evaluations are needed to reach the optimum.

Default Displayed Output

The default printed output produced by the CSSM procedure contains the following information:

- brief information about the input data set, including the data set name and label
- summary statistics for the response variables in the model, including the names of the variables, the total number of observations and the number of missing observations, the smallest and largest measurements, and the mean and standard deviation

- information about the index variable, including the index value of the first and the last observation, the maximum difference between the successive index values, the number of distinct index values, and the categorization of the data into regular, regular with replication, or irregular types
- estimates of the regression parameters if the model contains any predictors, including their standard errors, t statistics, and p -values
- convergence status of the likelihood optimization process if any parameters are estimated
- estimates of the free parameters at the end of the model-fitting phase, including the parameter estimates and their approximate standard errors
- the likelihood-based goodness-of-fit statistics, including the full likelihood, the sum of squares of residuals normalized by their standard errors, and the information criteria: AIC, AICC, HQIC, BIC, and CAIC
- summary of most significant additive outliers

Displayed Output

The CSSM procedure assigns a name to each table it creates. You can use these names to refer to the table when you use the Output Delivery System (ODS) to select tables and create output data sets. These names are listed in [Table 14.9](#).

Table 14.9 ODS Tables Produced by PROC CSSM

ODS Table Name	Description	Statement	Option
Tables That Summarize the Model Information			
ModelSummary	Summary information about the underlying state space model		Default
IdInformation	Summary information about the ID variable		Default
ResponseInfo	Summary information about the response variables		Default
StateSummary	Summary information about the model state vector	PROC CSSM	STATEINFO
DiffuseStateSummary	Summary information about the diffuse initial state	PROC CSSM	STATEINFO
Tables Related to Model Parameters and the Likelihood			
ConvergenceStatus	Convergence status of the estimation process		Default
RegressionEstimates	Estimates of the regression parameters	MODEL	Default
StateRegressionEstimates	Estimates of the state regression parameters	STATE	W

Table 14.9 *continued*

ODS Table Name	Description	Statement	Option
FixedStateEstimates	Estimates of time-invariant, non-stochastic state subsections		Default
NamedParameterEstimates	Estimates of the parameters specified in the PARMS statement	PARMS	Default
ParameterEstimates	Estimates of the unknown elements in the model system matrices		Default
DisturbanceCovariance	Estimate of the disturbance covariance	STATE	PRINT=COV
InitialCovariance	Estimate of the initial state covariance	STATE	PRINT=COV1
ARCoefficient	Estimate of the autoregressive coefficient matrix	STATE	PRINT=AR
MACoefficient	Estimate of the moving-average coefficient matrix	STATE	PRINT=MA
TransitionMatrix	Estimate of the state transition matrix	STATE	PRINT=T
FitSummary	Summary of the likelihood-based fit-statistics		Default
InformationCriteria	Likelihood-based information criteria		Default
Tables Related to Series and Component Forecasts			
Forecasts	Series forecasts	MODEL	PRINT=FILTER
SmoothedResponse	Smoothed series values	MODEL	PRINT=SMOOTH

ODS Graphics

Statistical procedures use ODS Graphics to create graphs as part of their output. ODS Graphics is described in detail in the “Statistical Graphics Using ODS” chapter in *SAS/STAT User’s Guide*.

Before you create graphs, ODS Graphics must be enabled (for example, by using the ODS GRAPHICS ON statement). For more information about enabling and disabling ODS Graphics, see the section “Enabling and Disabling ODS Graphics” in that chapter.

The overall appearance of graphs is controlled by ODS styles. Styles and other aspects of using ODS Graphics are discussed in the section “A Primer on ODS Statistical Graphics” in that chapter.

You can refer to every graph produced through ODS Graphics with a name. The names of the graphs that PROC CSSM generates are listed in [Table 14.10](#), along with the required statements and options.

Table 14.10 ODS Graphs Produced by PROC CSSM

ODS Graph Name	Description	Statement	Option
Graphs for One-Step-Ahead Residual Analysis			
ResidualNormalityPlot	Normality check	PROC CSSM	PLOTS=RESIDUAL(NORMAL)
ResidualHistogram	Residual histogram	PROC CSSM	PLOTS(UNPACK)=RESIDUAL
ResidualQQPlot	Residual Q-Q plot	PROC CSSM	PLOTS(UNPACK)=RESIDUAL
StdResidualPlot	Time series plot of standardized residuals	PROC CSSM	Default
Graphs Related to Outlier Detection and Structural Break			
PredErrorNormalityPlot	Normality check	PROC CSSM	PLOTS=AO(NORMAL)
PredErrorHistogram	Prediction error histogram	PROC CSSM	PLOTS(UNPACK)=AO
PredErrorQQPlot	Prediction error Q-Q plot	PROC CSSM	PLOTS(UNPACK)=AO
StdPredErrorPlot	Time series plot of standardized additive-outlier statistics	PROC CSSM	PLOTS=AO(STD)
MaximalShockPlot	Time series plot of maximal state shock chi-square statistics	PROC CSSM	PLOTS=MAXSHOCK

OUT= Data Set

You can use the OUT= option in the OUTPUT statement to store the series and component forecasts that are produced by PROC CSSM. Which columns are included in the data set depends on the model specification. The model can have one or more response variables, a variety of components that appear in the MODEL statement, and components specified by the EVAL statement. The OUT= data set contains the one-step-ahead and full-sample estimates of the response variables, and all these components.

The following list describes the columns of the data set:

- the BY variables
- the ID variable
- the OBSINDEX variable, if specified by the OBSINDEX statement
- the response series (more than one in the multivariate case)
- the following columns associated with the response series (the wildcard * is replaced by the name of one of the response variables):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the response series.
 - RESIDUAL_* contains the difference between the actual and forecast values.
 - StdErr_* contains the standard error of prediction.
 - Lower_* and Upper_* contain the lower and upper forecast confidence limits.
 - Smoothed_* contains the smoothed values of the response variable.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the response variable.
 - AO_* contains the additive outlier estimate.
 - StdErr_AO_* contains the standard error of the additive outlier estimate.
- the following columns associated with the components (the wildcard * is replaced by the name of one of the components):
 - FORECAST_* contains the one-step-ahead predicted values and the multistep forecasts of the component.
 - StdErr_* contains the standard error of prediction.
 - Smoothed_* contains the smoothed values of the component.
 - StdErr_Smoothed_* contains standard errors of the smoothed values of the component.
 - Smoothed_Lower_* and Smoothed_Upper_* contain the lower and upper confidence limits of the smoothed component.
- the maximal state shock chi-square statistics at distinct time points (this column is present only if the MAXSHOCK option is used in the OUTPUT statement)

Confidence limits are not produced for the smoothed series values or for the component forecasts; they are produced for the smoothed components.

Examples: CSSM Procedure

Example 14.1: Bivariate Basic Structural Model

This example illustrates how you can use the CSSM procedure to analyze a bivariate time series. The following data set contains two variables, `f_KSI` and `r_KSI`, which are measured quarterly, starting the first quarter of 1969. The variable `f_KSI` represents the quarterly average of the log of the monthly totals of the front-seat passengers killed or seriously injured during the car accidents, and `r_KSI` represents a similar number for the rear-seat passengers. The data set has been extended at the end with eight missing values, which represent four quarters, to cause the CSSM procedure to produce model forecasts for this span.

```

run;
```

These data have been analyzed in Durbin and Koopman (2012, chap. 8, sec. 3). The analysis presented here is similar. To simplify the illustration, the monthly data have been converted to quarterly data and two predictors (the number of kilometers traveled and the real price of petrol) are excluded from the analysis. You can also use PROC CSSM to carry out the more elaborate analysis in Durbin and Koopman (2012).

One of the original reasons for studying these data was to assess the effect on `f_KSI` of the enactment of a seat-belt law in February 1983 that compelled the front seat passengers to wear seat belts. A simple graphical inspection of the data (not shown here) reveals that `f_KSI` and `r_KSI` do not show a pronounced

upward or downward trend but do show seasonal variation, and that these two series seem to move together. Additional inspection also shows that the seasonal effect is relatively stable throughout the data span. These considerations suggest the following model for $y = (f_KSI, r_KSI)$:

$$y_t = \begin{pmatrix} X_t \\ 0 \end{pmatrix} \beta + \mu_t + \zeta_t + \xi_t$$

All the terms on the right-hand side of this equation are assumed to be statistically independent. These terms are as follows:

- The predictor X_t (defined as Q1_83_Shift later in the program) denotes a variable that is 0 before the first quarter of 1983, and 1 thereafter. X_t is supposed to affect only f_KSI (the first element of y); it represents the enactment of the seat-belt law of 1983.
- μ_t denotes a bivariate random walk. It is supposed to capture the slowly changing level of the vector y_t . To capture the fact that f_KSI and r_KSI move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of lower than full rank.
- ζ_t denotes a bivariate trigonometric seasonal term. In this model, it is taken to be fixed (that is, the seasonal effects do not change over time).
- ξ_t denotes a bivariate white noise term, which captures the residual variation that is unexplained by the other terms in the model.

The preceding model is an example of a (bivariate) basic structural model (BSM). The following statements load the seatBelt data into the table mylib.seatBelt:

```
data mylib.seatBelt;
  set seatBelt;
run;
```

The following statements specify and fit this model to f_KSI and r_KSI :

```
proc cssm data=mylib.seatBelt stateinfo;
  id date interval=quarter;
  Q1_83_Shift = (date >= '1jan1983'd);
  state error(2) type=WN cov(g) print=cov;
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) print=cov;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = Q1_83_Shift rw1 s1 wn1 / print=(smooth);
  model r_KSI = rw2 s2 wn2;
  eval f_KSI_sa = rw1 + Q1_83_Shift;
  output out=mylib.For1;
run;
```

The PROC CSSM statement specifies the input table, `mylib.seatBelt`. The use of the STATEINFO option in the PROC CSSM statement produces additional information about the model state vector and its diffuse initial state. The optional ID statement specifies an index variable, `date`. The INTERVAL=QUARTER option in the ID statement indicates that the measurements were collected on a quarterly basis. Next, a programming statement defines `Q1_83_Shift`, the predictor that represents the enactment of the seat-belt law of 1983. It is used later in the MODEL statement for `f_KSI`. Separate STATE statements specify the terms μ_t , ξ_t , and ζ_t because they are statistically independent. Each model that governs them (white noise for ξ_t , random walk for μ_t , and trigonometric seasonal for ζ_t) can be specified by using the TYPE= option of the STATE statement. When you use the TYPE= option, you can use the COV option to specify the information about the disturbance covariance in the state transition equation. The other details, such as the transition matrix specification and the specification of A_1 in the initial condition, are inferred from the TYPE= option. The use of PRINT=COV in the STATE statement causes the estimated disturbance covariance to be printed. For ξ_t (a white noise), A_1 is zero and $Q_t = Q$ for all $t \geq 1$, where Q is specified by the COV option. For μ_t and ζ_t the initial condition is fully diffuse—that is, A_1 is an identity matrix of appropriate order and $Q_1 = 0$. The total diffuse dimension of this model, $(d + k)$, is $9 = 8 + 1$ as a result of one predictor, `Q1_83_Shift`, and two fully diffuse state subsections, μ_t and ζ_t . The components in the model are defined by suitable linear combinations of these different state subsections. The program statements define the model as follows:

- **state error(2) type=WN cov(g);** defines ξ_t as a two-dimensional white noise, named `error`, with the covariance of general form. Then two COMPONENT statements define `wn1` and `wn2` as the first and second elements of `error`, respectively.
- **state level(2) type=RW cov(rank=1);** defines μ_t as a two-dimensional random walk, named `level`, with covariance of general form whose rank is restricted to 1. Then two COMPONENT statements define `rw1` and `rw2` as the first and second elements of `level`, respectively.
- **state season(2) type=season(length=4);** defines ζ_t as a two-dimensional trigonometric seasonal of season length 4, named `season`, with zero covariance—signified by the absence of the COV option. Then two COMPONENT statements define `s1` and `s2` as appropriate linear combinations of `season` so that `s1` represents the seasonal for `f_KSI` and `s2` represents the seasonal for `r_KSI`. Because TYPE=SEASON in the STATE statement, the COMPONENT statement appropriately interprets `component s1 = season[1];` as `s1` being a dot product: $(1\ 0\ 0\ 0\ 1\ 0) * \text{season}$. For more information, see the section “Multivariate Season” on page 783.
- **model f_KSI = Q1_83_Shift rw1 s1 wn1;** defines the model for `f_KSI`, and **model r_KSI = rw2 s2 wn2;** defines the model for `r_KSI`.

The CSSM procedure fits the model and reports the parameter estimates, their approximate standard errors, and the likelihood-based goodness-of-fit measures by default. In order to output the one-step-ahead and full-sample estimates of the components in the model, you can either use the PRINT= options in the MODEL statement and the respective COMPONENT statements or you can specify an output data set in the OUTPUT statement. In addition, you can use the EVAL statement to define specific linear combinations of the underlying state that should also be estimated. The statement `eval f_KSI_sa = rw1 + Q1_83_Shift;` is an example of one such linear combination. It defines `f_KSI_sa`, a linear combination that represents the seasonal adjustment of `f_KSI`. The output data set, `mylib.For1` (named in the OUTPUT statement) contains estimates of all the model components in addition to the estimate of `f_KSI_sa`.

The model summary table, shown in [Output 14.1.1](#), provides basic model information, such as the dimension of the underlying state equation ($m = 10$), the diffuse dimension of the model ($(d + k) = 9$), and the number of parameters (5) in the model parameter vector θ .

Output 14.1.1 Bivariate Basic Structural Model

Model Summary	
Number of Model Equations	2
State Dimension	10
Dimension of the Diffuse Initial Condition	9
Number of Parameters	5

Additional details about the role of different components in forming the model state and its diffuse initial condition are shown in [Output 14.1.2](#) and [Output 14.1.3](#). They show that the 10-dimensional model state vector is made up of subsections that are associated with error and level (each of dimension 2) and season (of dimension 6). Similarly, the nine-dimensional diffuse vector in the initial condition is made up of subsections that correspond to level, season, and the regression variable, Q1_83_Shift. Note that error does not contribute to the diffuse initial vector because it has a fully nondiffuse initial state.

Output 14.1.2 Bivariate Basic Structural Model State Vector Summary

State Vector Composition	
Subsection	Dimension
error	2
level	2
season	6

Output 14.1.3 Bivariate Basic Structural Model Initial Diffuse State Vector Summary

Diffuse Initial State Composition	
Subsection	Dimension
level	2
season	6
Q1_83_Shift	1

The index variable information is shown in [Output 14.1.4](#).

Output 14.1.4 Index Variable Information

ID Variable Information					
Name	Start	End	Maximum Distinct		Type
			Delta	Values	
date	1969/1	1985/4	1.0000	68	Regular

[Output 14.1.5](#) provides simple summary information about the response variables. It shows that f_KSI and r_KSI have four missing values each and no induced missing values because the predictor in the model, Q1_83_Shift, has no missing values.

Output 14.1.5 Response Variable Summary

Response Variable Information							
		Number of Observations		Induced Missing		Standard Deviation	
Name	Total	Missing	Missing	Minimum	Maximum	Mean	Deviation
f_KSI	68	4	0	6.164	7.093	6.707	0.2062
r_KSI	68	4	0	5.556	6.405	5.973	0.1862

The regression coefficient of Q1_83_Shift, shown in [Output 14.1.6](#), is negative and is statistically significant. This is consistent with the expected drop in f_KSI after the enactment of the seat-belt law.

Output 14.1.6 Regression Coefficient of Q1_83_Shift

Regression Parameter Estimates					
		Standard			
Response	Regressor	Estimate	Error	t Value	Pr > t
f_KSI	Q1_83_Shift	-0.4084	0.0259	-15.74	<.0001

[Output 14.1.7](#) shows the estimates of the elements of θ . The five parameters in θ correspond to unknown elements that are associated with the covariance matrices in the specifications of error and level. Whenever a covariance specification is of a general form and is not defined by a user-specified variable list, it is internally parameterized as a product of its Cholesky root: $\text{Cov} = \text{Root Root}^T$. This ensures that the resulting covariance is positive semidefinite. The Cholesky root is constrained to be lower triangular, with positive diagonal elements. If rank constraints (such as the rank-one constraint on the covariance in the specification of level) are imposed, the number of free parameters in the Cholesky factor is reduced appropriately. For more information, see the section “[Covariance Parameterization](#)” on page 793. In view of these considerations, the five parameters in θ are a result of three parameters from the Cholesky root of error and two parameters that are associated with the Cholesky root of level.

Output 14.1.7 Parameter Estimates

Model Parameter Estimates					
				Standard	
Component	Type	Parameter	Estimate	Error	t Value
error	Disturbance Covariance	RootCov[1, 1]	0.0361	0.0074	4.91
error	Disturbance Covariance	RootCov[2, 1]	0.0338	0.0113	2.99
error	Disturbance Covariance	RootCov[2, 2]	0.0462	0.0047	9.84
level	Disturbance Covariance	RootCov[1, 1]	0.0375	0.0084	4.45
level	Disturbance Covariance	RootCov[2, 1]	0.0223	0.0057	3.92

[Output 14.1.8](#) shows the resulting covariance estimate of error after multiplying the Cholesky factors.

Output 14.1.8 White Noise Covariance Estimate

Disturbance Covariance for error		
	Col1	Col2
Row1	0.00131	0.00122
Row2	0.00122	0.00328

Similarly, [Output 14.1.9](#) shows the covariance estimate of level disturbance. Note that because of the rank-one constraint, the determinant of this matrix is 0.

Output 14.1.9 Covariance Estimate of the Random Walk Disturbance

Disturbance Covariance for level		
	Col1	Col2
Row1	0.00141	0.000837
Row2	0.000837	0.000497

[Output 14.1.10](#) shows the likelihood computation summary. This table is produced by using the fitted model to carry out the filtering operation on the data. For more information, see the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769.

Output 14.1.10 Likelihood Computation Summary of the Fitted Model

Likelihood Computation Summary	
Nonmissing Response Values Used	128
Estimated Parameters	5
Initialized Diffuse State Elements	9
Normalized Residual Sum of Squares	119.0000
Diffuse Log Likelihood	166.1575
Profile Log Likelihood	199.9116

The output data set, `mylib.For1`, specified in the `OUTPUT` statement contains one-step-ahead and full-sample estimates of all the model components and the user-specified components (defined by the `EVAL` statement). Their standard errors and the upper and lower confidence limits (by default, 95%) are also produced.

The following statements use the `mylib.For1` data set to produce a time series plot of the seasonally adjusted `f_KSI`:

```
proc sgplot data=mylib.For1;
  title "Seasonally Adjusted f_KSI with 95% Confidence Band";
  band x=date lower=smoothed_lower_f_KSI_sa
    upper=smoothed_upper_f_KSI_sa ;
  series x=date y=smoothed_f_KSI_sa;
  refline '1jan1985'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
  scatter x=date y=f_KSI ;
run;
```

The generated plot is shown in [Output 14.1.11](#).

Output 14.1.11 Plot of Seasonally Adjusted f_KSI 

Example 14.2: Random-Effects and Autoregressive Models for Panel Data

This example shows how you can use the CSSM procedure to specify and fit the two-way random-effects model and the autoregressive model to analyze a panel of time series. The fitting of dynamic panel model for such data is illustrated in “[Example 14.11: Dynamic Panel Model for the Cigar Data](#)” on page 859. These (and a few other) model types can also be fitted by the PANEL procedure, a SAS/ETS procedure that is specially designed to efficiently handle the cross-sectional time series data. However, because of the differences in their model fitting algorithms, generally the parameter estimates and other fit statistics produced by the CSSM and PANEL procedures do not match. The CSSM procedure always uses the (restricted) maximum likelihood for parameter estimation. The estimation method used by the PANEL procedure depends on the model type and the particular estimation options.

The cross-sectional data, Cigar, that are used in the section “[Getting Started: CSSM Procedure](#)” on page 722 are reused in this example. The output shown here is less extensive than the output shown in that section. The main emphasis of this example is how you can specify the two-way random effects model and the autoregressive model in the CSSM procedure.

According to the two-way random effects model, the cigarette sales, $lsales$, can be described by the following equation:

$$lsales_{i,t} = \mu + lprice \beta_1 + lndi \beta_2 + lpimin \beta_3 + \zeta_i + \eta_t + \epsilon_{i,t}$$

This model represents $lsales$ in region i and in year t as a sum of an overall intercept μ , the regression effects due to $lprice$, $lndi$, and $lpimin$, a zero-mean, random effect ζ_i associated with region i , a zero-mean, random effect η_t associated with year t , and the observation noise $\epsilon_{i,t}$. The region-specific random effects ζ_i and the year-specific random effects η_t are assumed to be independent, Gaussian sequences with variances σ_ζ^2 and σ_η^2 , respectively. In addition, they are assumed to be independent of the observation noise, which is also assumed to be a sequence of independent, zero-mean, Gaussian variables with variance σ_ϵ^2 .

The following statements load the Cigar data into the table `mylib.Cigar`:

```
data mylib.Cigar;
  set Cigar;
run;
```

You can specify and fit this model by using the following statements:

```
proc cssm data=mylib.Cigar;
  id year interval=year;
  obsindex region;
  parms s2g/ lower=(1.e-6);
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  /* region-specific random effects */
  state zeta(46) T(I) cov1(I)=(s2g);
  component regionEffect = zeta * (RegionArray);
  /* year-specific random effect */
  state eta(1) type=wn cov(D);
  component timeEffect = eta[1];
  irregular wn;
  intercept = 1.0;
  model lsales = intercept lprice lndi lpimin
    timeEffect regionEffect wn;
run;
```

The `PARMS` statement defines `s2g`, a parameter that is restricted to be positive and is used later as the variance parameter for the region effect. Similarly the 46-dimensional array, `RegionArray`, of region-specific dummy variables is defined to be used later. The state subsection `zeta` corresponds to ζ , which is the 46-dimensional vector of region-specific, zero-mean, random effects. The component `regionEffect` extracts the proper element of ζ by using the array `RegionArray`. A constant column, `intercept`, is defined to be used later as an intercept term. The component `timeEffect` corresponds to η_t , and `wn` specifies the observation noise ϵ_{it} . Finally the `MODEL` statement defines the model. Some of the tables that are produced by running these statements are shown in [Output 14.2.1](#) through [Output 14.2.5](#).

The model summary, shown in [Output 14.2.1](#), shows that the model is defined by one `MODEL` statement, the dimension of the underlying state vector is 47 (because ζ is 46-dimensional and η_t is one-dimensional), the diffuse dimension is 4 (because of the four predictors in the model), and there are three parameters to be estimated.

Output 14.2.1 Two-Way Random-Effects Model: Model Summary

Model Summary	
Number of Model Equations	1
State Dimension	47
Dimension of the Diffuse Initial Condition	4
Number of Parameters	3

Output 14.2.2 provides the likelihood information about the fitted model.

Output 14.2.2 Two-Way Random-Effects Model: Likelihood Summary

Likelihood Computation Summary	
Nonmissing Response Values Used	1380
Estimated Parameters	3
Initialized Diffuse State Elements	4
Normalized Residual Sum of Squares	1376
Diffuse Log Likelihood	1459
Profile Log Likelihood	1471

Output 14.2.3 shows the regression estimates.

Output 14.2.3 Two-Way Random-Effects Model: Regression Estimates

Regression Parameter Estimates					
		Standard			
Response	Regressor	Estimate	Error	t Value	Pr > t
Isales	intercept	2.7976	0.1136	24.62	<.0001
Isales	lprice	-0.9029	0.0365	-24.73	<.0001
Isales	Indi	0.5922	0.0246	24.08	<.0001
Isales	lpimin	0.1266	0.0398	3.18	0.0015

The ML estimate of s2g, a parameter specified in the PARMS statement, is shown in Output 14.2.4. It corresponds to σ_{ξ}^2 , the variance of the region effect.

Output 14.2.4 Two-Way Random-Effects Model: Estimate of σ_{ξ}^2

Estimates of Named Parameters			
		Standard	
Parameter	Estimate	Error	t Value
s2g	0.0241	0.0051	4.70

Output 14.2.5 Variance Estimates of η_t and ϵ_{it}

Model Parameter Estimates					
		Standard			
Component	Type	Parameter	Estimate	Error	t Value
eta	Disturbance Covariance	Cov[1, 1]	0.0007	0.0003	2.58
wn	Irregular	Variance	0.0057	0.0002	25.40

The estimates of the other unknown parameters in the model are shown in [Output 14.2.5](#). It shows the estimate of the variance of the irregular component ω and the estimate of the variance of the time effect η_t .

The remainder of this example describes how you can specify and fit the following first-order vector autoregressive model to the cigarette data:

$$\begin{aligned} \text{lsales}_{i,t} &= \mu + \text{lprice} \beta_1 + \text{ln di} \beta_2 + \text{lpimin} \beta_3 + \zeta_t[i] \\ \zeta_t &= \Phi \zeta_{t-1} + \eta_t \end{aligned}$$

This model represents lsales in region i and in year t as a sum of an overall intercept μ , the regression effects due to lprice , ln di , and lpimin , and the i th element of a vector error term $\zeta_t[i]$. The multidimensional error sequence ζ_t is assumed to follow a first-order autoregression with a diagonal autoregressive coefficient matrix Φ and with a multivariate, white noise sequence η_t as its disturbance sequence. The covariance matrix of η_t , Σ , is assumed to be dense. Note that the dimension of the vectors ζ_t is the same as the number of cross sections in the study (the number of regions in this example). Therefore, even for a relatively modest panel study, the total number of parameters to be estimated can get quite large. Therefore, in this example only the first three regions are considered in the analysis. The following statements specify and fit this model to the Cigar data set:

```
proc cssm data=mylib.Cigar;
  where region <= 3;
  id year interval=year;
  obsindex region;
  array RegionArray{3} region1-region3;
  do i=1 to 3;
    RegionArray[i] = (region=i);
  end;
  state zeta(3) type=varma(p(d)=1) cov(g) print=(ar cov);
  component eta = zeta*(RegionArray);
  intercept = 1.0;
  model lsales = intercept lprice ln di lpimin eta;
run;
```

The vectors ζ_t are specified in the STATE statement. The TYPE= specification signifies that the three-dimensional state subsection, zeta , follows a vector AR(1) model with a diagonal transition matrix and a disturbance covariance of a general form. The PRINT=(AR COV) option causes the CSSM procedure to print the estimated AR coefficient matrix, Φ , and the disturbance error covariance Σ , respectively. The COMPONENT statement defines the appropriate error contribution (named eta), $\zeta_t[i]$. [Output 14.2.6](#) shows the estimated regression coefficients, [Output 14.2.7](#) shows the estimate of Φ , and [Output 14.2.8](#) shows the estimate of Σ :

Output 14.2.6 Autoregressive Model: Regression Estimates

Regression Parameter Estimates

Example 14.3: Backcasting, Forecasting, and Interpolation

This example illustrates how you can do model-based extrapolation—backcasting, forecasting, or interpolation—of a response variable. All you need is to appropriately augment the input data set with the relevant ID and predictor information and assign missing values to the response variable in these places. The following DATA step creates one such augmented data set by using a well-known data set that contains recordings of the Nile River water level measured between the years 1871 and 1970. Suppose you want to backcast the Nile water level for two years before 1871, forecast it for two years after 1970, and interpolate its value for the year 1921—for illustration purposes, this value is assumed to be missing in the available data set.

```
data Nile;
    input level @@;
    year = intnx( 'year', '1jan1869'd, _n_-1 );
    format year year4.;
    if year = '1jan1921'd then level=.;
datalines;
. .
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
831 726 456 824 702 1120 1100 832 764 821
768 845 864 862 698 845 744 796 1040 759
781 865 845 944 984 897 822 1010 771 676
649 846 812 742 801 1040 860 874 848 890
744 749 838 1050 918 986 797 923 975 815
1020 906 901 1170 912 746 919 718 714 740
. .
;
```

```
data mylib.Nile;
  set Nile;
run;
```

It is also known that for this time span the Nile water level can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements fit this model to the data:

```
proc cssm data=mylib.Nile;
  id year interval=year;
  shift1899 = ( year >= '1jan1899'd );
  trend rw(rw);
  irregular wn;
  model level = shift1899 RW wn / print=smooth;
  output out=mylib.nileOut;
quit;
```

The model-based interpolated and extrapolated values of the Nile water level are shown in [Output 14.3.1](#), which is produced by using the PRINT=SMOOTH option in the MODEL statement.

Output 14.3.1 Interpolated and Extrapolated Nile Water Level

Full-Sample Prediction of Missing Values for level				
ID	Estimate	Standard Error	95% Confidence Limits	
1869	1097.7	130.2	842.5	1353
1870	1097.7	130.2	842.5	1353
1921	851.1	128.9	598.6	1104
1971	851.1	128.9	598.6	1104
1972	851.1	128.9	598.6	1104

Example 14.4: Smoothing of Repeated Measures for Longitudinal Data

This example of a repeated measures study is taken from Diggle, Liang, and Zeger (1994, p. 100). The data consist of body weights of 27 cows, measured at 23 unequally spaced time points over a period of approximately 22 months. Following Diggle, Liang, and Zeger (1994), one animal is removed from the analysis, one observation is removed according to their Figure 5.7, and the time is shifted to start at 0 and is measured in 10-day increments. The design is a 2×2 factorial, and the factors are the infection of an animal with *M. paratuberculosis* and whether the animal is receiving iron dosing. The data set contains five variables: cow assigns a unique identification number—from 1 to 26—to each cow in the study, tpoint denotes the time of the growth measurement, weight denotes the growth measurement, iron is a dummy variable that indicates whether the animal is receiving iron or not, and infection is a dummy variable that indicates whether the animal is infected or not. The goal of the study is to assess the effect of iron and infection—and their possible interaction—on weight. The following DATA steps create this data set:

```

data times;
  input time1-time23;
  datalines;
122 150 166 179 219 247 276 296 324 354 380 445
478 508 536 569 599 627 655 668 723 751 781
;

data Cows;
  if _n_ = 1 then merge times;
  array t{23} time1 - time23;
  array w{23} weight1 - weight23;
  input cow iron infection weight1-weight23 @@;
  do i=1 to 23;
    weight = w{i};
    tpoint = (t{i}-t{1})/10;
    output;
  end;
  keep cow iron infection tpoint weight;
  datalines;
1 0 0 4.7 4.905 5.011 5.075 5.136 5.165 5.298 5.323
      5.416 5.438 5.541 5.652 5.687 5.737 5.814 5.799
... more lines ...

```

The following DATA step adds ironInf, a grouping variable that is used later during the plotting of the results. In the next step, the data are sorted by the index variable, tpoint.

```

data Cows;
  set Cows;
  ironInf = "No Iron and No Infection";
  if iron=1 and infection=1 then ironInf = "Iron and Infection";
  else if iron=1 and infection=0 then ironInf = "Iron and No Infection";
  else if iron=0 and infection=1 then ironInf = "No Iron and Infection";
  else ironInf = "No Iron and No Infection";
  run;

proc sort data=Cows;
  by tpoint ;
run;

```

The following statements load the Cows data into the table mylib.Cows:

```

data mylib.Cows;
  set Cows;
  obsNo = _n_;
run;

```

To assess the effect of iron and infection on weight, the natural growth profile of the animals must also be accounted for. Here two alternate models for this problem are considered. The first model assumes that the observed weight of an animal is the sum of a common growth profile, which is modeled by a polynomial spline trend of order 2, the regression effects of iron and infection, and the observation error—modeled as white noise. An interaction term, for interaction between iron and infection, was found to be insignificant and is not included. In the second model, the common growth profile and the regression variables of the first

model are replaced by four environment specific growth profiles.

The following statements fit the first model:

```
proc cssm data=mylib.Cows;
  id tpoint;
  obsindex obsNo;
  trend growth(ps(2));
  irregular wn;
  model weight = iron infection growth wn;
  eval pattern = iron + infection + growth;
  output out=mylib.For;
quit;
```

Output 14.4.1 shows that the state dimension of this model is 2 (corresponding to the polynomial trend specification of order 2), the number of diffuse elements in the initial condition is 4 (corresponding to the trend and the two regressors iron and infection), and the number of unknown parameters is 2 (corresponding to the variance parameters of trend and irregular).

Output 14.4.1 Model1: Model Summary Information

Model Summary	
Number of Model Equations	1
State Dimension	2
Dimension of the Diffuse Initial Condition	4
Number of Parameters	2

Output 14.4.2 shows that the ID variable is irregularly spaced with replication.

Output 14.4.2 ID Variable Information

ID Variable Information					
Name	Start	End	Maximum Distinct		
			Delta	Values	Type
tpoint	0	65.900000	6.5000	23	Irregular with Replication

The estimated regression coefficients of iron and infection, shown in Output 14.4.3, are significant and negative. This implies that both iron and infection adversely affect the response variable, weight.

Output 14.4.3 Model 1: Regression Estimates

Regression Parameter Estimates					
Response	Regressor	Estimate	Standard		
			Error	t Value	Pr > t
weight	iron	-0.0748	0.0076	-9.82	<.0001
weight	infection	-0.1292	0.0086	-15.04	<.0001

The variance estimates of the trend component and the irregular component are shown in Output 14.4.4.

Output 14.4.4 Model 1: Estimates of Unnamed Parameters

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
growth	PS(2) Trend	Level Variance	0.0000	0.0000	1.80
wn	Irregular	Variance	0.0086	0.0005	17.06

After examining the model fit, it is useful to study how well the patterns implied by the model follow the data. `pattern`, defined by the `EVAL` statement, is a sum of the trend component and the regression effects. A graphical examination of the smoothed estimate of `pattern` is done next. The following `DATA` step merges the output data set specified in the `OUTPUT` statement, `mylib.For`, with the input data set, `mylib.Cows`. In particular, this adds `ironInf` (a grouping variable from `mylib.Cows`) to `mylib.For`.

```
data mylib.For;
  merge mylib.for mylib.Cows;
  by tpoint obsNo;
run;
```

The following statements produce the graphs of `smoothed_pattern`, grouped according to the environment condition (see [Output 14.4.5](#)). The plot clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.”

```
proc sgplot data=mylib.For noautolegend;
  title 'Common Growth Profile Adjusted by Iron and Infection Status';
  band x=tpoint lower=smoothed_lower_pattern
      upper=smoothed_upper_pattern / group=ironInf name="band";
  series x=tpoint y=smoothed_pattern / group=ironInf name="series";
  keylegend "series";
run;
```

Output 14.4.5 Model 1: Growth Profile Comparison with 95% Confidence Bands

The following statements produce a panel of plots that show how well `smoothed_pattern` follows the observed data:

```
proc sgpanel data=mylib.For noautolegend;
  title 'Growth Plots Grouped by Iron and Infection';
  label tpoint='Time' ;
  panelby iron infection / columns=2;
  band x=tpoint lower=smoothed_lower_pattern
        upper=smoothed_upper_pattern ;
  scatter x=tpoint y=weight;
  series x=tpoint y=smoothed_pattern ;
run;
```

Output 14.4.6 shows that the model fits the data reasonably well.

Output 14.4.6 Model 1: Smoothed Model Fit Lines

The following statements fit the second model. In this model separate polynomial trends are fit according to different settings of iron and infection by specifying an appropriate list of (dummy) variables in the **CROSS=** option of the trend specification.

```
proc cssm data=mylib.Cows;
  id tpoint;
  obsindex obsNo;
  a1 = (iron=1 and infection=1);
  a2 = (iron=1 and infection=0);
  a3 = (iron=0 and infection=1);
```

```

a4 = (iron=0 and infection=0);
trend growth(ps(2)) cross=(a1-a4);
irregular wn;
model weight = growth wn;
/* Define contrasts between a1 and other treatments */
comp a1Curve = growth_state_[1];
comp a2Curve = growth_state_[2];
comp a3Curve = growth_state_[3];
comp a4Curve = growth_state_[4];
eval contrast21 = a2Curve - a1Curve;
eval contrast31 = a3Curve - a1Curve;
eval contrast41 = a4Curve - a1Curve;
output out=mylib.for1;
quit;

```

As a result of the **CROSS=** option, the trend component growth is actually a sum of four separate trends that correspond to the different iron-infection settings. Denoting growth by μ_t and the four independent trends by $\mu_{1,t}$, $\mu_{2,t}$, $\mu_{3,t}$, and $\mu_{4,t}$,

$$\mu_t = a1 * \mu_{1,t} + a2 * \mu_{2,t} + a3 * \mu_{3,t} + a4 * \mu_{4,t}$$

where a1, a2, a3, and a4 are the dummy variables specified in the **CROSS=** option. This shows that, for any given setting (say, the one for a4) μ_t is simply the corresponding trend $\mu_{4,t}$. In addition, note the form of the **COMPONENT** statements that define the components a1Curve, a2Curve, a3Curve, and a4Curve. This form of the **COMPONENT** statement treats the state that is associated with growth, named growth_state_ by convention, as a state of nominal dimension 4—the number of variables in the **CROSS=** list. This, in turn, implies that a1Curve, which is defined as growth_state_[1], refers to $\mu_{1,t}$. These components are subsequently used in the **EVAL** statements to define contrasts between the trends—for example, contrast21 corresponds to the difference between the trends $\mu_{2,t}$ and $\mu_{1,t}$. The estimates of these components (a1Curve, a2Curve, ..., contrast41) are output to the data set mylib.For1 named in the **OUT=** option of the **OUTPUT** data set.

The model summary, shown in [Output 14.4.7](#), reflects the increased state dimension and the increased number of parameters.

Output 14.4.7 Model2: Model Summary Information

Model Summary	
Number of Model Equations	1
State Dimension	8
Dimension of the Diffuse Initial Condition	8
Number of Parameters	5

[Output 14.4.8](#) shows the parameter estimates for this model.

Output 14.4.8 Model2: Estimates of Unnamed Parameters (Partial Output)

Component	Type	Parameter	Estimate	StdErr	tValue
growth(Cross = a1)	PS(2) Trend	Level Variance	0.0000	0.0000	1.87
growth(Cross = a2)	PS(2) Trend	Level Variance	0.0000	0.0000	2.29
growth(Cross = a3)	PS(2) Trend	Level Variance	0.0000	0.0000	2.14
growth(Cross = a4)	PS(2) Trend	Level Variance	0.0000	0.0000	2.49
wn	Irregular	Variance	0.0084	0.0005	16.84

Next, the smoothed estimate of trend (growth) is graphically studied. The following DATA step prepares the data for the grouped plots of smoothed_growth by merging mylib.For1 with the input data set Cows. As before, the reason is merely to include ironInf (the grouping variable).

```
data mylib.For1;
  merge mylib.For1 mylib.Cows;
  by tpoint obsNo;
run;
```

The following statements produce the graphs of smoothed μ_t for the desired settings (since the grouping variable ironInf exactly corresponds to these settings). Once again, the plot in [Output 14.4.9](#) clearly shows that the control group “No Iron and No Infection” has the best growth profile, while the worst growth profile is for the group “Iron and Infection.” However, unlike the first model, the profile curves are not merely shifted versions of a common profile.

```
proc sgplot data=mylib.For1 noautolegend;
  title 'Iron and Infection Status-Specific Growth Profiles';
  band x=tpoint lower=smoothed_lower_growth
    upper=smoothed_upper_growth / group=ironInf name="band";
  series x=tpoint y=smoothed_growth / group=ironInf name="series";
  keylegend "series";
run;
```

Output 14.4.9 Model 2: Growth Profile Comparison with 95% Confidence Bands

The following statements produce the plot of smoothed $(\mu_{4,t} - \mu_{1,t})$ —contrast between the best and the worst growth profiles:

```
proc sgplot data=mylib.For1;
  title "Estimated Contrast between the Treatments 4 and 1 ";
  band x=tpoint lower=smoothed_lower_contrast41
    upper=smoothed_upper_contrast41;
  series x=tpoint y=smoothed_contrast41;
run;
```

Output 14.4.10 shows that the growth pattern of the control group “No Iron and No Infection” consistently remains above the growth pattern of the treatment group “Iron and Infection.”

Output 14.4.10 Estimated Contrast between the Treatments 4 and 1 with 95% Confidence Bands

Example 14.5: A User-Defined Trend Model

This example shows how to specify a continuous-time trend model discussed in Harvey (1989, chap. 9, sec. 9.2.1). This model is not one of the predefined trend models in the CSSM procedure. The system matrices that govern the two-dimensional state of this model are

$$\mathbf{T} = \begin{bmatrix} 1 & h \\ 0 & 1 \end{bmatrix}$$

$$\mathbf{Q} = \begin{bmatrix} h\sigma_1^2 + \frac{h^3\sigma_2^2}{3} & \frac{h^2\sigma_2^2}{2} \\ \frac{h^2\sigma_2^2}{2} & h\sigma_2^2 \end{bmatrix}$$

where $h = h_t = (\tau_{t+1} - \tau_t)$ denotes the difference between the successive time points, and the parameters σ_1^2 and σ_2^2 are called the level variance and the slope variance, respectively. The initial condition is fully diffuse. The trend component corresponds to the first element of this state vector. The second element of the state vector corresponds to the slope of this trend component. This model reduces to the polynomial spline model of order 2 if the level variance $\sigma_1^2 = 0$. (See the section “[Polynomial Spline Trend](#)” on page 778.)

The following statements specify a trend-plus-noise model to model the growth of cows in the previous example (“[Example 14.4: Smoothing of Repeated Measures for Longitudinal Data](#)” on page 814). The only cows that are considered are the ones that received iron and are infected.

```
data mylib.Cows;
  set Cows;
  obsNo = _n_;
run;

proc cssm data=mylib.Cows;
  where iron=1 and infection=1;
  id tpoint;
  obsindex obsNo;
  parms var1 var2 / lower=(1.e-8 1.e-8);
  array tMat{2,2};
  tMat[1,1] = 1;
  tMat[2,2] = 1;
  tMat[1,2] = _ID_DELTA_;
  array covMat{2,2};
  covMat[1,1] = var1*_ID_DELTA_ + var2*_ID_DELTA_**3/3;
  covMat[1,2] = var2*_ID_DELTA_**2/2;
  covMat[2,1] = covMat[1,2] ;
  covMat[2,2] = var2*_ID_DELTA_;
  state harveyLL(2) T(g)=(tMat) cov(g)=(covMat) a1(2);
  component trend = harveyLL[1];
  component slope = harveyLL[2];
  irregular wn;
  model weight = trend wn;
  output out=mylib.for;
run;
```

The program is easy to follow. The PARMS statement declares var1 and var2 as positive parameters, which correspond to σ_1^2 and σ_2^2 , respectively. The programming statements define arrays tMat and covMat, which later become the matrices **T** and **Q**, respectively. Note that the element tMat[2,1] is left unassigned, since it is a structural zero of **T** (see the section “[Sparse Transition Matrix Specification](#)” on page 765 for more information). Recall that the predefined variable _ID_DELTA_ contains the value of h_t , which is needed for defining the elements of **T** and **Q** (see the section “[ID Statement](#)” on page 743). The STATE statement defines the trend state vector, harveyLL, and the COMPONENT statement defines the trend component, trend, by selecting the first element of harveyLL. An additional COMPONENT statement defines the slope component, slope, as the second element of harveyLL. The slope component (which represents the cow’s growth rate) is not part of the observation equation; it is specified so that its estimate is output to For (the OUT= data set specified in the OUTPUT statement). The IRREGULAR statement defines the observation noise, and the MODEL statement defines the trend-plus-noise model.

The estimates of var1 and var2 are shown in [Output 14.5.1](#). It shows that the estimate of the level variance is nearly 0, implying that the fitted trend model is identical to the polynomial spline trend of order 2.

Output 14.5.1 Estimates of the Named Parameters

Estimates of Named Parameters			
Parameter	Estimate	Standard Error	t Value
var1	0.0000	0.0008	0.00
var2	0.0000	.	.

The estimate of the noise variance is shown in [Output 14.5.2](#).

Output 14.5.2 Estimates of the Unnamed Parameters

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
wn	Irregular	Variance	0.0095	0.0009	10.49

The following statements produce the plot of the fit of this trend model (shown in [Output 14.5.3](#)):

```
proc sgplot data=mylib.For;
  title "Model Fit: Two-Parameter Polynomial Spline of Order 2";
  series x=tpoint y=smoothed_trend;
  scatter x=tpoint y=weight;
run;
```

Output 14.5.3 A User-Defined Trend Model

The following statements produce the plot of the estimate of the slope component (shown in [Output 14.5.4](#)). This plot complements the preceding plot of trend; it shows the pattern of decline in the growth rate as the animals age.

```
proc sgplot data=mylib.For;
  title "Smoothed Estimate of Growth-Rate";
  series x=tpoint y=smoothed_slope;
run;
```

Output 14.5.4 Estimate of the slope Component

Example 14.6: Model with Multiple ARIMA Components

This example shows how you can fit the REGCOMPONENT models in Bell (2011) by using the CSSM procedure. The following DATA step generates the data used in the last example of this article (Example 6: “Modeling a Time Series with a Sampling Error Component”). The variable *y* in this data set contains monthly values of the VIP series (value of construction put in place), a US Census Bureau publication that measures the value of construction installed or erected at construction sites during a given month. The values of *y* are known to be contaminated with heterogeneous sampling errors; the variable *hwt* in the data set is a proxy for this sampling error in the log scale. The variable *hwt* is treated as a weight variable for the noise component in the model.

```
data Test;
  input y hwt;
  date = intnx('month', '01jan1997'd, _n_-1 );
  format date date.;
  logy = log(y);
  label logy = 'Log value of construction put in place';
  datalines;
```

```

115.2    0.042
110.4    0.042
111.5    0.067
127.9    0.122
150.0    0.129
149.5    0.135
139.5    0.152
144.6    0.168
176.0    0.173

... more lines ...

```

The following statements load the Test data into the table mylib.Test:

```

data mylib.Test;
  set Test;
run;

```

The article proposes the following model for the log VIP series:

$$\log(y) = \mu_t + hwt * \eta_t$$

where μ_t follows an $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ model and η_t is a zero-mean, AR(2) error process. In addition, the article fixes the values of some of the model parameters to known values in order to use the known background information. The following statements specify the model in the article:

```

proc cssm data=mylib.Test;
  id date interval=month;
  parm var1=0.016565 / lower=1.e-8;
  trend airlineTrend(arma(d=1 sd=1 q=1 sq=1 s=12)) variance=var1;
  trend ar2Noise(arma(p=2)) cross=(hwt) ar=0.600 0.246 variance=0.34488;
  model logy = airlineTrend ar2Noise;
  output outfor=mylib.For;
run;

```

Output 14.6.1 Estimates of the MA Parameters in the airlineTrend Model

Model Parameter Estimates				
Component	Type	Parameter	Estimate	Standard Error t Value
airlineTrend	ARMA Trend	MA_1	0.4660	0.2798 1.67
airlineTrend	ARMA Trend	SMA_1	0.4298	0.3440 1.25

Output 14.6.2 Estimate of the Error Variance in the airlineTrend Model

Estimates of Named Parameters			
Parameter	Estimate	Standard Error	t Value
var1	0.0053	0.0031	1.74

The $\text{ARIMA}(0,1,1) \times (0,1,1)_{12}$ trend μ_t is named airlineTrend and the zero-mean, AR(2) error process η_t is named ar2Noise. For more information about the ARIMA notation, see the [TREND](#) statement. The estimates

of model parameters are shown in [Output 14.6.1](#) and [Output 14.6.2](#). These estimates are quite close to the estimates given in the article, and the estimated trend and noise series are also very similar to those in the article.

The following statements produce the plot of the estimate of the `airlineTrend` component (shown in [Output 14.6.3](#)). This plot is very similar to the trend plot shown in the article (the article plots are in the antilog scale).

```
proc sgplot data=mylib.For;
  title "Smoothed Estimate of the ARIMA(0,1,1)(0,1,1)12 Trend";
  series x= date y=smoothed_airlineTrend;
  scatter x= date y=logy;
run;
```

Output 14.6.3 Estimate of the `airlineTrend` Component

The following statements produce the plot of the estimate of the `ar2Noise` component (shown in [Output 14.6.4](#)). This plot is also very similar to the noise plot shown in the article (once again, the article plots are in the antilog scale).

```
proc sgplot data=mylib.For;  
  title "Smoothed Estimate of the AR(2) Noise";  
  series x= date y=smoothed_ar2Noise;  
  refline 0;  
run;
```

Output 14.6.4 Estimate of the ar2Noise Component

Example 14.7: A Dynamic Factor Model for the Yield Curve

This example shows how you can fit a variant of the dynamic Nelson-Siegel (DNS) factor model discussed in Koopman, Mallee, and van der Wel (2010). Also see the example in Durbin and Koopman (2012, chap. 8, sect. 6). The following DATA step creates the yield-curve data set, `Dns`, that is used in Koopman, Mallee, and van der Wel. The data are monthly bond yields that were recorded between the start of 1970 and the end of 2000 for 17 bonds of different maturities; the maturities range from three months to 10 years (120 months). The variable `date` contains the observation date, `yield` contains the bond yield, `maturity` contains the associated bond maturity, and `mtype` contains an index (ranging from 1 to 17) that sequentially labels bonds of increasing maturity. The data have been extended for two more years by adding missing yields for the years 2001 and 2002, which causes the CSSM procedure to produce model forecasts for this span.

```
data Dns;
input date : date. yield maturity mtype;
format date date.;
datalines;
1-Jan-70      8.019      3      1
1-Jan-70      8.091      6      2
1-Jan-70      8.108      9      3

... more lines ...
```

In addition, suppose you are interested in extrapolating the fitted model to predict the yield of a hypothetical bond that has a maturity of 42 months and is not traded on the general exchange. The following DATA step creates the necessary missing values for this new bond, which is assigned the index of 18—that is, the value of `mtype` is 18:

```
data tmp1;
  set dns(keep=date);
  by date;
  if first.date then do;
    yield = .;
    maturity = 42;
    mtype = 18;
    output;
  end;
run;

proc append data=tmp1 base=dns; run;
proc sort data=dns;
by date;
run;
```

Suppose that $\theta_t(\tau)$ denotes the (idealized) yield at time t that is associated with a bond of maturity τ (in months). Even if time is not measured continuously and the bonds of only certain maturities are traded, $\theta_t(\tau)$ is treated as a smooth function of two continuous variables, time t and maturity τ . Koopman, Mallee, and van der Wel (2010) discuss a variety of models for $\theta_t(\tau)$, which is called the yield surface. One of these models depends on a positive, time-varying, scalar parameter λ_t and a time-varying three-dimensional vector

parameter β_t . This model can be described as follows:

$$\begin{aligned}\theta_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) \\ &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right)\end{aligned}$$

This model is a dynamic version of a static model discussed in Nelson and Siegel (1987), where λ_t and β_t are time invariant. For fixed time period t , the three terms in this model have relatively simple interpretation. The first term β_{1t} can be thought of as the overall yield level because it does not depend on τ , the bond maturity. It can also be thought of as the long term yield because as $\tau \uparrow \infty$ the other two terms vanish; the coefficients of both β_{2t} and β_{3t} converge to 0 as $\tau \uparrow \infty$ (recall that λ_t is positive). Next, note that as $\tau \downarrow 0$ the coefficient of β_{2t} in the second term converges to 1 while that of β_{3t} in the third term converges to 0; therefore the second term can be thought of as a correction to the overall yield that is associated with the short term bonds. Finally, note that the coefficient of β_{3t} in the third term is a unimodal function of τ that decays monotonically to 0 as $\tau \downarrow 0$ and as $\tau \uparrow \infty$; therefore the third term is associated with the medium term bond yields. It is postulated that the observed yield, denoted by $y_t(\tau)$, is a noisy version of this unobserved (true) yield $\theta_t(\tau)$. The observed yield can be modeled as

$$\begin{aligned}y_t(\tau) &= \theta(\tau; \lambda_t, \beta_t) + \epsilon_{t,\tau} \\ &= \beta_{1t} + \beta_{2t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \right) + \beta_{3t} \left(\frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau) \right) + \epsilon_{t,\tau} \\ (\beta_t - \mu) &= \Phi(\beta_{t-1} - \mu) + \eta_t\end{aligned}$$

where $\epsilon_{t,\tau}$ are zero-mean, independent, Gaussian variables with variance σ_τ^2 , and η_t is a three-dimensional, Gaussian white noise. That is, β_t is a VAR(1) process with mean vector μ . The remainder of this example explains how to use the CSSM procedure to fit this model to the yield data in the Dns data set.

Suppose that variables Z1, Z2, and Z3 are defined as the coefficients of β_{1t} , β_{2t} , and β_{3t} , respectively. That is,

$$\begin{aligned}Z1 &= 1 \\ Z2 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} \\ Z3 &= \frac{1 - \exp(-\lambda_t \tau)}{\lambda_t \tau} - \exp(-\lambda_t \tau)\end{aligned}$$

In this case,

$$\theta_t(\tau) = Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t}$$

Let $\zeta_t = \beta_t - \mu$. Then ζ_t is a zero-mean VAR(1) process and $\beta_t = \zeta_t + \mu$. In particular,

$$\begin{aligned}\theta_t(\tau) &= Z1 * \beta_{1t} + Z2 * \beta_{2t} + Z3 * \beta_{3t} \\ &= Z1 * \zeta_{1t} + Z2 * \zeta_{2t} + Z3 * \zeta_{3t} + Z1 * \mu_1 + Z2 * \mu_2 + Z3 * \mu_3\end{aligned}$$

This shows that the model for $y_t(\tau)$ can be cast into a state space form with the following observation equation:

$$y_t(\tau) = \mathbf{Z}\zeta_t + \mathbf{Z}\mu + \epsilon_{t,\tau}$$

The underlying six-dimensional state vector α_t is formed by joining the two independent subvectors, ζ_t (which is a zero-mean, VAR(1) process) and the constant mean vector μ . That is, $\alpha_t = (\zeta_{1t} \zeta_{2t} \zeta_{3t} \mu_1 \mu_2 \mu_3)'$.

Note that the variables Z2 and Z3 depend on the time varying parameter λ_t , which is unknown. λ_t is assumed to be a smooth and positive function of time t . In what follows λ_t is represented as an exponential of a cubic spline—a B-spline—in time with four evenly spaced interior knots between January 1970 and December 2002. A cubic spline with four interior knots can be represented as a sum of seven (number of knots + spline degree + 1) B-spline basis functions, $c_{1t}, c_{2t}, \dots, c_{7t}$, for example. More specifically, λ_t can be expressed as

$$\lambda_t = \exp(v1 * c_{1t} + \dots + v7 * c_{7t})$$

for some parameters $v1, v2, \dots, v7$ and the B-spline basis functions (of time) $c_{1t}, c_{2t}, \dots, c_{7t}$. Thus, the variables Z2 and Z3 become known functions of time, except for the parameters $v1, v2, \dots, v7$, which are estimated from the data. The following statements augment the Dns data set with the B-spline basis columns in two steps. First a data set that contains the basis columns, c1–c7, is created by using the BSPLINE function in the IML procedure. This data set is then merged with the Dns data set.

```
proc iml;
  use dns;
  read all var {date} into x;
  bsp = bspline(x, 2, ., 4);
  create spline var{c1 c2 c3 c4 c5 c6 c7};
  append from bsp;
quit;
data dns;
  merge dns spline;
run;
```

The following statements load the Dns data into the table mylib.Dns:

```
data mylib.Dns;
  set Dns;
run;
```

The following statements use the CSSM procedure to perform the model fitting and forecasting calculations. The variance of the observation equation disturbance for the hypothetical bond (mtype = 18) is taken to be the average of the neighboring bonds (mtype = 10 and 11), whose maturities are 36 and 48 months, respectively.

```
proc cssm data=mylib.Dns optimizer(technique=activeset) like=marginal;
  id date interval=month;
  obsindex mtype;

  /* Time-varying parameter lambda */
  parms v1-v7;
  lambda = exp(v1*c1 + v2*c2 + v3*c3 + v4*c4
              + v5*c5 + v6*c6 + v7*c7);

  /* Observation equation disturbance -- separate variance for each maturity */
  parms signal-signal17 / lower=1.e-4;
  array s_array(17) signal-signal17;
  do i=1 to 17;
    if (mtype=i) then sigma = s_array[i];
  end;
  if (mtype=18) then sigma = (signal10+signal11)/2;
```

```

irregular wn variance=sigma;

/* Variables Z1, Z2, Z3 needed in the observation equation */
Z1= 1.0;
tmp = lambda*maturity;
Z2 = (1-exp(-tmp))/tmp;
Z3 = ( 1-exp(-tmp)-tmp*exp(-tmp) )/tmp;

/* Zero-mean VAR(1) factor zeta and the associated component */
state zeta(3) type=VARMA(p=1) cov(g) print=(cov ar);
comp zetaComp = (Z1-Z3)*zeta;

/* Constant mean vector mu and the associated component */
state mu(3) type=rw;
comp muComp = (Z1-Z3)*mu;

/* Observation equation */
model yield = muComp zetaComp wn;

/* Various components defined only for output purposes */
eval yieldSurface = muComp + zetaComp;

comp zeta1 = zeta[1];
comp zeta2 = zeta[2];
comp zeta3 = zeta[3];
comp mu1 = mu[1];
comp mu2 = mu[2];
comp mu3 = mu[3];

comp z2zeta = (Z2)*zeta[2];
comp z3zeta = (Z3)*zeta[3];
comp z2Mu = (Z2)*mu[2];
comp z3Mu = (Z3)*mu[3];

eval beta1 = mu1 + zeta1;
eval beta2 = mu2 + zeta2;
eval beta3 = mu3 + zeta3;

eval shortTem = z2zeta + z2Mu;
eval medTerm = z3zeta + z3Mu;

/* output the component estimates and the forecasts */
output out=mylib.dnsFor pdv;
run;

```

The ACTIVESET optimization technique is used for parameter estimation since it is computationally more efficient in this example. The mean vector μ (recall that $\mathbf{beta}_t = \mathbf{zeta}_t + \mu$) is specified as a three-dimensional random walk with zero disturbance covariance (signified by the absence of COV= option). The model specification part of the program ends with the MODEL statement; the subsequent COMP and EVAL statements define some useful linear combinations of the underlying state. Their estimates are computed after the model fit is completed and are output to the output data set mylib.dnsFor. The mylib.dnsFor data set also contains all the program variables and the parameters defined in the PARMS statement because the

OUTPUT statement contains the PDV option.

Output 14.7.1 shows the estimated mean vector (μ). It shows that the mean long-term yield is 7.64. Output 14.7.2 shows the estimates of v_1 – v_7 (used for defining time-varying λ_t) and the maturity specific observation variances. Output 14.7.3 shows the estimate of the VAR(1) transition matrix Φ , and Output 14.7.4 shows the associated disturbance covariance matrix Σ . The model fit summary is shown in Output 14.7.5.

Output 14.7.1 Estimate of the Mean Vector (μ)

The following statements produce the time series plots of the smoothed estimate of the idealized bond yield ($\theta_t(\tau)$) for bonds with maturities 30, 60, and 120 months (shown in [Output 14.7.6](#)). To simplify the display, the plots exclude the time span prior to 1991.

```
proc sgplot data= mylib.dnsFor;
  title "The Estimated Yield Surface and the Observed Yields ";
  where maturity in (3 60 120) and date >= '31dec1990'd;
  series x=date y=smoothed_yieldSurface / group=maturity;
  scatter x=date y=yield / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 14.7.6 Smoothed Estimate of $\theta_t(\tau)$ for $\tau = 3, 60, 120$ 

The plots indicate that the DNS model is a reasonable description of the yield data. Similar plots (not shown here) for other maturities also indicate the adequacy of the DNS model. The following statements produce the time series plot of the smoothed estimate of β_{1t} , the long-term bond yield (shown in [Output 14.7.7](#)) :

```
proc sgplot data=mylib.dnsFor;
  title "Long-Term Bond Yields Over Time ";
  series x=date y=smoothed_beta1 ;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 14.7.7 Smoothed Estimate of β_{1t} , the Long-Term Yield

Similarly, [Output 14.7.8](#), which is produced by the following statements, shows the smoothed estimate of the correction to the overall yield that is provided by the second term ($Z_2 * \beta_{2t}$) for maturities of 3 months and 120 months. As expected, the correction for the (long-term) maturity of 120 months is negligible compared to the (short-term) maturity of 3 months.

```
proc sgplot data=mylib.dnsFor;
  title "The Correction Term for the Short-Term Yields ";
  where maturity in (3 120);
  series x=date y=smoothed_shortTem / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 14.7.8 Smoothed Estimate of $Z_2 * \beta_{2t}$, the Correction Term for the Short-Term Yields

The following statements create plots that show the estimated yield for the hypothetical bond whose maturity is 42 months:

```
proc sgplot data=mylib.dnsFor;
  title "Interpolated Yield Curve for the Bond of 42 Months' Maturity";
  title2 "(With 95% Pointwise Confidence Band)";
  where maturity in (42);
  band x=date lower=smoothed_lower_yieldSurface upper=smoothed_upper_yieldSurface;
  series x=date y=smoothed_yieldSurface;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;

proc sgplot data= mylib.dnsFor;
  title "Estimated Yield Curves";
  title2 "(Maturities 36, 42, and 48 Months)";
  where maturity in (36 42 48) and date >= '31dec1990'd;
  series x=date y=smoothed_yieldSurface / group=maturity;
  refline '31dec2000'd / axis=x lineattrs=GraphReference(pattern = Dash)
    name="RefLine" label="Start of multistep forecasts";
run;
```

Output 14.7.9 shows the interpolated yield curve with a pointwise 95% confidence band. In the historical period, the confidence band appears too tight, mostly because of graphical scaling.

Output 14.7.9 Interpolated Yield Curve for 42 Months' Maturity

Output 14.7.10 Estimated Yield Curves

Output 14.7.10 shows the estimates of $\theta_t(\tau)$ for $\tau = 36, 42$, and 48 months. As expected, the estimated $\theta_t(42)$ lies between the estimates of $\theta_t(36)$ and $\theta_t(48)$.

Example 14.8: Diagnostic Plots and Structural Break Analysis

This example provides information about the diagnostic plots that the CSSM procedure produces. In addition, a simple illustration of structural break analysis is also provided. For additional examples of structural break analysis, see Selukar (2017). The following plots are available in the CSSM procedure:

- a panel of two plots—a histogram and a Q-Q plot—for the normality check of the one-step-ahead residuals $v_{t,i}$. A separate panel is produced for each response variable.
- a time series plot of standardized residuals, one per response variable
- a panel of two plots—a histogram and a Q-Q plot—for the normality check of the prediction errors $AO_{t,i}$. A separate panel is produced for each response variable.
- a time series plot of standardized prediction errors, one per response variable

- a time series plot of maximal state shock chi-square statistics

All these plots are used primarily for model diagnostics. In this example, the automobile seat-belt data that are discussed in “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803 are revisited. In “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803, the question under consideration is whether the data show evidence of the effectiveness of the seat-belt law that was introduced in the first quarter of 1983. An intervention variable, `Q1_83_Shift`, was used in the model to measure the effect of this law on the drivers and front-seat passengers who were killed or seriously injured in car accidents (`f_KSI`). In the current example, the analysis of these data begins without the knowledge of this seat-belt law. In effect, the same model is fitted without the use of the intervention variable `Q1_83_Shift`.

```
data mylib.seatBelt;
  set seatBelt;
run;
```

The following statements specify the model (without the intervention variable):

```
proc cssm data= mylib.seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
  state level(2) type=RW cov(rank=1) checkbreak;
  component rw1 = level[1];
  component rw2 = level[2];
  state season(2) type=season(length=4);
  component s1 = season[1];
  component s2 = season[2];
  model f_KSI = rw1 s1 wn1;
  model r_KSI = rw2 s2 wn2;
run;
```

The `PLOTS=ALL` option in the `PROC CSSM` statement turns on all the plotting options. Because there are two response variables, nine plots in total are produced: a separate set of four plots—two residual and two prediction error—is produced for `f_KSI` and `r_KSI`, and one maximal shock plot is produced. Only three of these plots are shown here. [Output 14.8.1](#) shows the normality check for the one-step-ahead residuals for `f_KSI`. It shows some evidence of lack of normality.

Output 14.8.1 Normality Check of One-Step-Ahead Residuals for f_KSI 

Output 14.8.2 shows the time series plot of standardized prediction errors for f_KSI . It identifies some extreme observations (additive outliers): two near 1983 and one near 1970.

Output 14.8.2 Time Series Plot of Standardized Prediction Errors for f_KSI 

Output 14.8.3 shows the time series plot of maximal shock statistics. This plot can be very informative in showing the temporal locations of the structural changes in the overall observation-generation process (treating the fitted model as the reference). It can indicate locations of shifts in the process level or shifts in other characteristics, such as its slope. The precise nature of the shift (whether the shift occurs in the level or in some other aspects) can be determined by using the CHECKBREAK option in the appropriate STATE and TREND statements (as is done in the STATE statement in this example that defines the bivariate state level). In this example, the maximal shock statistics plot indicates two locations—the last quarter of 1973 and the first quarter of 1983—as likely locations for the structural breaks that are associated with the traffic accident process. These are indeed reasonable findings, because the last quarter of 1973 (beginning in October 1973) is associated with the start of the oil crisis that severely curtailed worldwide automobile traffic, and the first quarter of 1983 is associated with the introduction of the seat-belt law that might have improved the safety of drivers and front-seat passengers. In addition, **Output 14.8.4** shows the summary of most likely break locations for the bivariate state level. It identifies a break in the first element of level (which corresponds to the drivers and front-seat passengers) in the first quarter of 1983.

Output 14.8.3 Time Series Plot of Maximal Shock Statistics**Output 14.8.4** Elementwise Break Summary for the Bivariate State: level

Elementwise Break Summary for level			
Element			
ID	Index	Z Value	Pr > z
1983/1	1	-5.85	<.0001

The following statements fit a revised model that accounts for the break in the first element of level by introducing a dummy variable, Q1_83_Pulse, in the state equation:

```
ods output ElementStateBreakDetails=stateBreak;
proc cssm data= mylib.seatBelt optimizer(tech=interiorpoint) plots=all;
  id date interval=quarter;
  Q1_83_Pulse = (date = '1jan1983'd);
  zero = 0;
  state error(2) type=WN cov(g);
  component wn1 = error[1];
  component wn2 = error[2];
```

```

state level(2) type=RW cov(rank=1) W(g)=(Q1_83_Pulse zero)
  checkbreak print=breakdetail;
component rw1 = level[1];
component rw2 = level[2];
state season(2) type=season(length=4);
component s1 = season[1];
component s2 = season[2];
model f_KSI = rw1 s1 wn1;
model r_KSI = rw2 s2 wn2;
run;

```

Note that using Q1_83_Pulse in the definition of level is equivalent to using Q1_83_Shift in the MODEL statement for f_KSI in “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803. [Output 14.8.5](#) shows the estimated change in the first element of the state level, which is the same as the estimated level shift shown in [Output 14.1.6](#) (this is not surprising, because these two models are statistically equivalent).

Output 14.8.5 Estimate of the Regression Coefficient of Q1_83_Pulse

Estimate of the State Equation Regression Vector					
State	Element Index	Estimate	Standard Error	t Value	Pr > t
level	1	-0.4084	0.0259	-15.74	<.0001

In the preceding CSSM procedure statements, the CHECKBREAK option is used along with the PRINT=BREAKDETAIL option, which produces a table that contains the break statistics at every distinct time point (this table, in turn, is captured in the output data set stateBreak for later use). [Output 14.8.6](#) shows the time series plot of maximal shock statistics for this revised model. As expected, the plot no longer shows the first quarter of 1983 as a structural break location. It continues to show the last quarter of 1973 as a structural break location, because the fitted model does not try to explicitly account for this shift.

Output 14.8.6 Time Series Plot of Maximal Shock Statistics for the Model with Q1_83_Pulse

Note that the reference line in [Output 14.8.3](#) is drawn at the 99.9th percentile, whereas the reference line in [Output 14.8.6](#) is drawn at the 99th percentile. The reference line location in the maximal state shock chi-square statistics plot is based on the points in the plot. A reference line is drawn at percentile 80, 90, 99, or 99.9 based on the largest maximal shock statistic that is shown.

The detailed information in the data set `stateBreak` can be used to further investigate the possibility of significant breaks in the trend in and around 1973. The following statements produce scatter plots for the break statistics for both the drivers and front passengers and the rear passengers (reference lines are also drawn at -3 and 3 to check for extreme Z values):

```
proc sgpanel data=stateBreak;
  panelby elementIndex;
  scatter x=time y=zValue;
  refline 3 / axis=y lineattrs=(pattern=shortdash) noclip;
  refline -3 / axis=y lineattrs=(pattern=shortdash) noclip;
run;
```

Output 14.8.7 Elementwise Structural Break Statistics for level

The resulting graph, shown in [Output 14.8.7](#), shows possible breaks in the second element—rear side passengers—around 1969. In general, however, the evidence of breaks in the elements of level is not very strong. This means that you must look elsewhere to explain the extreme point in [Output 14.8.6](#).

Example 14.9: Variable Bandwidth Smoothing for Longitudinal Data

The data for this example, taken from Givens and Hoeting (2005, chap. 11, Example 11.8), contain two variables, x and y . The variable y represents noisy evaluation of an unknown smooth function at x . The data are sorted by x .

```
data Difficult;
input x y;
datalines;
0.002 0.040
0.011 0.009
0.013 0.719
0.016 0.199
0.017 -0.409
```

... more lines ...

Output 14.9.1 shows the scatter plot of y against x that is generated by the following statements:

```
proc sgplot data=Difficult;
  title "Scatter Plot of Y versus X";
  scatter x=x y=y ;
run;
```

Output 14.9.1 Scatter Plot of Y versus X

The plot clearly shows that the variance of y values varies considerably over the range of x values—the variance is larger for x values around 0.2 and gets increasingly smaller as the x values get closer to 1. Givens and Hoeting (2005) discuss the difficulties of extracting a smooth pattern from such data. Consider the following model for y :

$$y(x) = \mu_x + \epsilon_x$$

where μ_x is a smooth trend component and ϵ_x is the observation noise with variance, $h(x)$, which changes with x : $\epsilon_x \sim N(0, h(x))$. It is known (Durbin and Koopman 2012, chap. 3, sect. 9 and chap. 8, sect. 5) that modeling the trend μ_x as a polynomial smoothing spline (for example, the way the growth curves are

modeled in “[Example 14.4: Smoothing of Repeated Measures for Longitudinal Data](#)” on page 814) and taking the variance function of the observation noise ϵ_x a constant results in a trend estimate that can be termed a fixed-bandwidth-smoother. The optimal bandwidth turns out to be a function of the signal-to-noise ratio: the ratio of the observation noise variance and the disturbance variance of the trend component. On the other hand, allowing the variance function of the observation noise to change with the x values results in a trend estimate that can be termed a variable-bandwidth-smoother. The rest of this example shows how to use the CSSM procedure to create a data-dependent variance function $h(x)$ and to extract the associated (variable-bandwidth) smooth trend from such data. Suppose that the (unknown) variance function $h(x)$ can be approximated as

$$h(x) = \exp\left(\sum_{i=1}^7 v_i \text{SplineBasis}_i(x)\right)$$

where $v_i, i = 1, 2, \dots, 7$ are unknown parameters and $\text{SplineBasis}_i(x), i = 1, 2, \dots, 7$, are the full set of cubic spline basis functions (B-splines) with four evenly spaced internal knots between the range of x values—essentially, four equispaced points between 0.0 and 1.0. Note that the number of basis functions in the full set, 7, is the sum of the number of internal knots, 4, and the degree of the polynomial, 3. The following statements create a data set, Combined, that contains the variables x and y , along with the desired spline basis functions (col1–col7) that are created by using the BSPLINE function in PROC IML:

```
proc iml;
  use difficult;
  /* read x and y from difficult into temp */
  read all var _num_ into temp;
  x = temp[,1];
  /* generate B-spline basis for a cubic spline
     with 4 evenly spaced internal knots in the x-range */
  bsp = bspline(x, 2, ., 4);
  Combined = temp || bsp;
  /* create a merged data set with x, y, and
     spline basis columns */
  create Combined var {x y col1 col2 col3 col4 col5 col6 col7};
  append from Combined;
quit;
```

The following statements load the Combined data into the table mylib.Combined:

```
data mylib.Combined;
  set Combined;
  index = _n_;
run;
```

The following statements specify and fit the desired model to the data:

```
proc cssm data=mylib.Combined opt(tech=dbldog);
  id x;
  obsindex index;
  /* parameters needed to define h(x) */
  parms v1-v7;
  /* defining h(x) */
  evar = exp(v1*col1 + v2*col2 + v3*col3 + v4*col4
            + v5*col5 + v6*col6 + v7*col7);
  /* defining the polynomial spline trend */
```

```

trend trend(ps(2));
/* defining the observation noise with variance h(x) */
irregular wn variance=evar;
model y = trend wn;
output out=mylib.For pdv;
run;

```

Output 14.9.2 shows the estimates of $v_i, i = 1, 2, \dots, 7$, and Output 14.9.3 shows the estimate of the disturbance variance associated with the polynomial spline trend that is specified in the TREND statement.

Output 14.9.2 Estimates of v1–v7

Estimates of Named Parameters

Component	Type	Parameter	Estimate	Standard	
				Error	t Value
trend	PS(2) Trend	Level Variance	338.6239	110.3375	3.07

The following statements produce a plot, shown in Output 14.9.4, of the fitted trend with 95% confidence band:

```

proc sgplot data=mylib.For;
  title "Variable Bandwidth Smoothing Spline";
  band x=x lower=smoothed_lower_trend
      upper=smoothed_upper_trend ;
  series x=x y=smoothed_trend;
  scatter x=x y=y;
run;

```

Output 14.9.4 Fitted Trend with 95% Confidence Band

Clearly the fitted curve tracks the data quite well. Lastly, [Output 14.9.5](#) (produced by using the following statements) shows the estimated variance function $h(x)$.

```
proc sgplot data=mylib.For;
  title "Estimated Variance Function";
  series x=x y=evar;
run;
```

As expected, the curve attains its peak at an x value around 0.18 and decays to nearly 0 as x values reach 1.0.

Output 14.9.5 Estimated Variance Function $h(x) = \exp(\sum_{i=1}^7 \hat{v}_i \text{SplineBasis}_i(x))$ 

Example 14.10: A Transfer Function Model for the Gas Furnace Data

This example describes how you can include components in your model that follow a transfer function model. Transfer function models, a generalization of distributed lag models, are useful for capturing the contributions from lagged values of the predictor series. Box and Jenkins popularized ARIMA models with transfer function inputs in their famous book (Box and Jenkins 1976). This example shows how you can specify an ARIMA model that is suggested in that book to analyze the data collected in an experiment at a chemical factory. The data set, called Series J by Box and Jenkins, contains sequentially recorded measurements of two variables: x , the input gas rate, and y , the output CO_2 . For the output CO_2 , Box and Jenkins suggest the model

$$y_t = \mu + f_t + \zeta_t$$

where μ is the intercept, ζ_t is a zero-mean noise term that follows a second-order autoregressive model (that is, $\zeta_t \sim \text{AR}(2)$), and f_t follows a transfer function model

$$f_t = \frac{(\gamma_1 B^3 + \gamma_2 B^4 + \gamma_3 B^5)}{(1 - \delta B)} x_t$$

The model for f_t is specified by using the ratio of two polynomials in the backshift operator B . Alternatively, this model can also be described as follows:

$$f_t = \delta f_{t-1} + \gamma_1 x_{t-3} + \gamma_2 x_{t-4} + \gamma_3 x_{t-5}$$

In this alternate form, it is easy to see that the equation for f_t can also be seen as a state evolution equation for a one-dimensional state with a (1×1) transition matrix δ and state regression variables x_{t-3} , x_{t-4} , and x_{t-5} (lagged values of x). This state equation has no disturbance term.

The following statements define the data set `Seriesj`. The variables `x3`, `x4`, and `x5`, which denote the appropriately lagged values of `x`, are also created. These variables are used later in the `STATE` statement that is used to specify f_t .

```
data Seriesj;
  input x y @@;
  label x = 'Input Gas Rate'
        y = 'Output CO2';
  x3 = lag3(x);
  x4 = lag4(x);
  x5 = lag5(x);
  obsIndex = _n_;
  label obsIndex = 'Observation Index';
datalines;
-0.109 53.8 0.000 53.6 0.178 53.5 0.339 53.5
0.373 53.4 0.441 53.1 0.461 52.7 0.348 52.4
0.127 52.2 -0.180 52.0 -0.588 52.0 -1.055 52.4

... more lines ...
```

The following statements load the `Seriesj` data into the table `mylib.Seriesj`:

```
/* Load data into mylib */
data mylib.Seriesj;
  set Seriesj(firstobs=6);
run;
```

The following CSSM procedure statements carry out the modeling of y , the output CO_2 , according to the preceding model:

```
proc cssm data=mylib.Seriesj;
  id obsIndex;
  parms delta /lower=-0.9999 upper=0.9999;
  state tfstate(1) T(g)=(delta) W(g)=(x3 x4 x5) a1(1) checkbreak;
  comp tfinput = tfstate[1];
  trend ar2(arma(p=2)) ;
  intercept = 1;
  model y = intercept tfinput ar2 ;
  eval modelCurve = intercept + tfinput;
  forecast out=mylib.For;
run;
```

The coefficient of the denominator polynomial, δ , is specified in a `PARMS` statement. It is constrained to be less than 1 in magnitude, which ensures that the transfer function term does not have explosive growth. The transfer function model for f_t is specified in a `STATE` statement that defines a one-dimensional state

named `tfstate`. In this statement, the transition matrix (which contains only one element, δ) is specified by using the `T(g)=` option; the state regression variables `x3`, `x4`, and `x5` are specified by using the `W(g)=` option; and the `CHECKBREAK` option is used to turn on the search for unexpected changes in the behavior of f_t . The `COV` option is absent from this `STATE` statement because the disturbance term is absent from the state equation for f_t . Moreover, because nothing can be assumed about the initial condition of this state equation, it is taken to be diffuse (as signified by the `A1` option). Note that the first five observations of the input data set, `Seriesj`, are excluded from the analysis to ensure that the state regression variables `x3`, `x4`, and `x5` do not contain any missing values. The component that is associated with `tfstate`, named `tfinput`, is specified in a `COMPONENT` statement that follows the `STATE` statement. A zero-mean, second-order autoregressive noise term, named `ar2`, is specified by using a `TREND` statement. Next, a constant regression variable, `intercept`, is defined to be used in the `MODEL` statement to capture the intercept term μ . Finally, the model specification is completed by specifying the response variable, `y`, and the three right-hand terms in the `MODEL` statement. Next, an `EVAL` statement is used to specify a component, `modelCurve`, which is the sum of the intercept and the transfer function input ($\mu + f_t$). The `modelCurve` component represents the structural part of the model and is defined only for output purposes: its estimate is output (along with the estimates of other components) to the data set that is specified in the `OUT=` option of the `OUTPUT` statement.

Note that the modeling of output CO_2 according to this model is also illustrated in “Example 7.3: Model for Series J Data from Box and Jenkins” (Chapter 7, *SAS/ETS User’s Guide*) of the PROC ARIMA documentation (see Chapter 7, “ARIMA Procedure” (*SAS/ETS User’s Guide*)). The ARIMA procedure handles the computation of the transfer function f_t slightly differently than the way it is estimated by the CSSM procedure. However, despite this algorithmic difference in the modeling procedures, for this example the estimated parameters agree quite closely (barring the sign conventions that are used to specify the model parameters).

Output 14.10.1 shows the estimate of μ , the intercept in the model. Output 14.10.2 shows the estimate of δ , the coefficient in the denominator polynomial of the transfer function. Output 14.10.3 shows the regression estimates of the state regression variables `x3`, `x4`, and `x5` (which correspond to the coefficients of the numerator polynomial). Output 14.10.4 shows the estimates of the parameters of the AR(2) noise term.

Output 14.10.1 Estimate of μ

ar2	ARMA Trend	Error Variance	0.0581	0.0049	11.96
ar2	ARMA Trend	AR_1	1.5319	0.0470	32.60
ar2	ARMA Trend	AR_2	-0.6291	0.0497	-12.65

The following statements produce a time series plot of the estimate of modelCurve—that is, the estimate of the structural part of the model ($\mu + f_t$)—along with the scatter plot of the observed values of the output CO₂. The plot, shown in [Output 14.10.5](#), seems to indicate that the model captures the relationship between the input gas rate and the output CO₂ quite well, at least up to the observation index 250.

```
proc sgplot data=mylib.For;
  title "Smoothed estimate of the model curve: Intercept + Transfer Function Input";
  series x=obsIndex y=smoothed_modelCurve;
  scatter x=obsIndex y=y;
run;
```

Output 14.10.5 Smoothed Estimate of $\mu + f_t$ 

The plot shown in [Output 14.10.6](#) shows the estimate of the noise term, ar_2 , which is produced by the following statements:

```
proc sgplot data=mylib.For;
  title "Smoothed estimate of the AR(2) Noise Term";
  series x=obsIndex y=smoothed_ar2;
  refline 0 / axis=y lineattrs=GraphReference(pattern = Dash);
run;
```

If you compare the scales of these two plots, it appears that the noise term is relatively small and that most of the variation in output CO₂ can be explained by the structural part of the model. It does, however, appear that the model fit deteriorates toward the latter part of the sample. The structural break analysis summary, shown in [Output 14.10.7](#), indicates strong evidence of structural break in the behavior of f_t at or near the observation index 264. Obviously, this type of structural break analysis can be quite useful in industrial quality-control applications.

Output 14.10.6 Smoothed Estimate of the AR(2) Noise Term**Output 14.10.7** Summary of Breaks in f_t

198.000000	1	-3.15	0.0016

Example 14.11: Dynamic Panel Model for the Cigar Data

This example shows how you can use the CSSM procedure to specify and fit the so-called dynamic panel model, which is commonly used to analyze a panel of time series. Suppose that a panel of time series $y_{t,i}$ follows the model

$$y_{t,i} = \rho y_{(t-1),i} + \mu_i + \beta X_{t,i} + \zeta_t + \epsilon_{t,i}$$

where t denotes the time index (for example, $t = 1, \dots, T$); i denotes the panel index (for example, $i = 1, \dots, P$); ρ is the autoregression coefficient; μ_i denote the panel-specific intercepts; $X_{t,i}$ are observations on a regression variable with regression coefficient β (the same for all panels); ζ_t are unobserved, random time effects; and $\epsilon_{t,i}$ are the observation errors. The sequences ζ_t and $\epsilon_{t,i}$ are assumed to be independent, zero-mean Gaussian variables with variances σ_1^2 and σ_0^2 , respectively. This is an example of a dynamic panel model that contains one regressor variable. It is easy to formulate this model equation as a state equation with state α_t of size P —the number of panels. Taking $y_{t,i} = \alpha_t[i]$, it is easy to see that the states α_t evolve according to the equation

$$\alpha_{t+1} = \mathbf{T}\alpha_t + \mathbf{W}_{t+1}\beta + \eta_{t+1}$$

where $\mathbf{T} = \rho \mathbf{I}_P$ (a P -dimensional, diagonal matrix with all its diagonal elements equal to ρ); $\mathbf{W}_t = (\mathbf{X}_t \ \mathbf{I}_P)$ is a $P \times (1 + P)$ -dimensional matrix (in a block form) of state regression variables, where the first block is a column that includes all the values $X_{t,i}$ that are associated with a given time index (t) and the second block is a P -dimensional identity matrix; $\beta = (\beta \ \mu_1, \dots, \mu_P)'$ is the $(1 + P)$ -dimensional column vector of regression coefficients; and $\eta_t = (\zeta_t + \epsilon_{t,1}, \dots, \zeta_t + \epsilon_{t,P})'$ is a P -dimensional column vector of all the disturbances that are associated with time index t . Because ζ_t and $\epsilon_{t,i}$ are independent, the covariance matrix of η_t —for example, $\mathbf{Q}_t$ —is easy to calculate: $\mathbf{Q}_t[i, i] = \sigma_0^2 + \sigma_1^2$ and, for $i \neq j$, $\mathbf{Q}_t[i, j] = \sigma_1^2$. This formulation can be easily extended to multiple regression variables, such as r variables, by appropriately modifying the term that is associated with the state regression variables— $\mathbf{W}_t\beta$: the new $\mathbf{W}_t$ matrix becomes $P \times (r + P)$ -dimensional and the new regression vector β becomes $(r + P)$ -dimensional.

The cross-sectional data, Cigar, that are used in the section “Getting Started: CSSM Procedure” on page 722 are reused in this example. In order to use the CSSM procedure to perform the dynamic panel model-based analysis, the input data set must be reorganized so that it contains the variables that form the $P \times (r + P)$ -dimensional matrix $\mathbf{W}_t$. For the Cigar data, the number of panels $P = 46$ (the number of regions considered in the study), and the number of regression variables $r = 3$. Therefore, the input data set needs to be augmented by $46 * (3 + 46) = 2,254$ variables that constitute the matrix $\mathbf{W}_t = (\mathbf{X}_t \ \mathbf{I}_{46})$ —the first 46×3 -dimensional block $\mathbf{X}_t$ contains the values of the three regression variables, lprice, lndi, and lpimin, at a given time index (a particular year in this case). The following DATA steps accomplish this task in two steps. In the first step, the raw data that form the rows of the Cigar data set are read into a temporary data set, Tmp, such that all $6*46 = 276$ values that are associated with a given year (values of six variables—year, region, lsales, lprice, lndi, and lpimin for 46 panels in a given year) are read in a single row that consists of 276 columns. In the second step, the final input data set is formed by rearranging Tmp so that it contains the necessary variables in the proper order—year (the time index), region (the panel index), lsales (the response variable), and the variables that form the 46×49 -dimensional $\mathbf{W}$ matrix (w1, ..., w2254).

```
data Tmp;
    input u1-u276;
datalines;
63 1 4.54223 3.35341 7.3514 3.26194
```

```
63 2 4.82831 3.17388 7.5729 3.21487
63 3 4.63860 3.29584 7.3000 3.25037
```

```
... more lines ...
```

```
data cigar(keep=year region lsales w1-w2254);
  array wmat{46, 49} w1-w2254;
  array ivar{46, 6} u1-u276;
  set tmp;
  year = intnx( 'year', '1jan63'd, u1-63 );
  format year year.;
  do i=1 to 46;
    region = ivar[i, 2];
    lsales = ivar[i, 3];
    do j=1 to 46;
      do k=1 to 49;
        wmat[j,k] = 0;
        if k = j+3 then wmat[j,k] = 1;
        if k=1 then wmat[j,k] = ivar[j, 4];
        if k=2 then wmat[j,k] = ivar[j, 5];
        if k=3 then wmat[j,k] = ivar[j, 6];
      end;
    end;
    output;
  end;
run;
```

The following statements load the Cigar data into the table mylib.Cigar:

```
/* Load data into mylib */
data mylib.Cigar;
  set Cigar;
run;
```

The following statements specify and fit the dynamic panel model:

```
proc cssm data=mylib.Cigar opt (tech=dbldog maxiter=75);
  id year interval=year;
  obsindex region;
  parms rho / lower=-0.9999 upper=0.9999;
  parms sigma0 sigma1 / lower=1.e-8;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  array cov{46,46};
  do i=1 to 46;
    do j=1 to 46;
      if(i=j) then cov[i,j] = sigma0 + sigma1;
      else cov[i,j] = sigma1;
    end;
  end;
  state panelState(46) T(I)=(rho) W(g)=(w1-w2254)
    cov(g)=(cov) al(46) checkbreak;
```

```

    comp dynPanel = (RegionArray)*panelState;
    model lsales = dynPanel;
    output out=mylib.for1 press;
run;

```

The estimates of the regression coefficients and the regional intercepts, which are all statistically significant, are shown in [Output 14.11.1](#). In particular, the estimated coefficients of `lprice`, `lndi`, and `lpimin`, are -0.26 , 0.13 , and 0.07 , respectively.

Output 14.11.1 Estimates of β_1 , β_2 , β_3 and the Regional Intercepts

Finally, you can compare the fit of the dynamic panel model with the fit of the model that is discussed in the section “Getting Started: CSSM Procedure” on page 722. Output 14.11.3 shows the likelihood-based information criteria for the dynamic panel model, and Output 14.11.4 shows the same information for the other model.

Output 14.11.3 Likelihood-Based Information Criteria: Dynamic Panel Model

Information Criteria		
Statistic	Diffuse Likelihood	Profile Likelihood
AIC (lower is better)	-4733	-4856
BIC (lower is better)	-4717	-4344
AICC (lower is better)	-4733	-4841
HQIC (lower is better)	-4727	-4665
CAIC (lower is better)	-4714	-4246

Output 14.11.4 Likelihood-Based Information Criteria: Getting Started Example

Information Criteria		
Statistic	Diffuse Likelihood	Profile Likelihood
AIC (lower is better)	-4488	-4145
BIC (lower is better)	-4478	-3638
AICC (lower is better)	-4488	-4130
HQIC (lower is better)	-4484	-3955
CAIC (lower is better)	-4476	-3541

Similarly, Output 14.11.5 shows fit criteria based on the delete-one cross validation error for the dynamic panel model, and Output 14.11.6 shows the same information for the other model.

Output 14.11.5 Delete-One Cross Validation Criteria: Dynamic Panel Model

Cross Validation Error Criteria			
		Generalized	
Variable	N	PRESS	Cross-Validation
Isales	1380	1.115	5.628E-07

Output 14.11.6 Delete-One Cross Validation Criteria: Getting Started Example

Cross Validation Error Criteria			
		Generalized	
Variable	N	PRESS	Cross-Validation
Isales	1380	1.29	6.181E-07

On the basis of both these considerations, the dynamic panel model appears to provide a better fit for the Cigar data than the model that is fit in the section “[Getting Started: CSSM Procedure](#)” on page 722.

Example 14.12: Long-Term Temperature Trends Based on a Multivariate Model

In a presentation by Ansley and de Jong (2015), three monthly time series are jointly modeled to obtain long-term—several decades long—temperature predictions for certain regions of the northern hemisphere. This example shows how you can specify and fit the final model that this presentation proposed. The following data set, `Temp`, contains four variables: `date` dates the monthly observations; `UAH` contains monthly satellite global temperature readings, starting in December 1978; `CRU` contains monthly temperature data, starting in January 1850 (from a different source); and `GISS` contains monthly temperature data, starting in January 1880 (from yet another source). All these temperature data are scaled suitably so that the numbers represent temperature readings in centigrade.

```
data Temp;
input UAH CRU GISS @@;
date = intnx('month', '01jan1850'd, _n_-1);
format date date.;
datalines;
.      8.243      .
.      9.733      .

... more lines ...
```

The following statements produce scatter plots of these three series in a single graph:

```
proc sgplot data=Temp;
  title "Scatter Plots of the Temperature Series";
  scatter x=date y=cru;
  scatter x=date y=uah ;
  scatter x=date y=giss;
run;
```

Output 14.12.1 shows the resulting graph. As already noted, these three series start at different points in the past. However, they all end at the same time: they all have measurements until January 2012, which is the last month in the data set. The mean levels of these series are different: the GISS measurements are generally larger than CRU and UAH by about 4 degrees. In addition, the variability in the CRU values seems to decrease with time (this is more apparent when the series is plotted by itself). The goal of the analysis is to use these data to make long-term predictions about future temperature levels. The following statements append 1,200 missing measurements to Temp, so that the model fitted by using the CSSM procedure can be extrapolated to obtain temperature forecasts 100 years in the future:

```
data append(keep=date cru giss uah);
  do i=1 to 1200;
    cru = .; giss=.; uah=.;
    date = intnx('month','01jan2012'D, i);
    format date monyy7.;
    output;
  end;
run;

proc append base=Temp data=Append; run;
```

Output 14.12.1 Scatter Plots of CRU, UAH, and GISS

Ansley and de Jong propose a parsimonious model that links these three time series. It can be described as

$$\begin{aligned}\text{GISS}_t &= \mu_t + a \zeta_t + a r_1 \epsilon_{1t} \\ \text{CRU}_t &= \beta_{cru} + \mu_t + a \zeta_t + a \epsilon_{2t} \\ \text{UAH}_t &= \beta_{uah} + \mu_t + a \zeta_t + a r_3 \epsilon_{3t}\end{aligned}$$

where β_{cru} and β_{uah} are intercepts that are associated with CRU and UAH, respectively; μ_t is an integrated random walk trend; ζ_t is a zero-mean, autoregressive noise term (which is scaled by an unknown scaling factor a); and ϵ_{it} ($i = 1, 2, 3$) are independent observation errors with different variances that are also scaled suitably. Note that the trend μ_t and the autoregressive noise term ζ_t are shared by the models of the three series, and, for identification purposes, the intercept for GISS is taken to be zero. In addition, the model parameters are assumed to be interrelated and are parameterized in a particular way (which leads to fewer parameters to estimate, and their relative scaling helps in parameter estimation). This special parameterization can be expressed as a function of seven basic parameters: *loga1*, *logr1*, *logr3*, *logsigma*, *b*, *c*, and *rhoParm* (this naming convention is different from that used by Ansley and de Jong (2015)).

Let $\sigma^2 = \exp(2\text{logsigma})$, and let the scaling factors $a = \exp(\text{loga1})$, $r_1 = \exp(\text{logr1})$, and $r_3 = \exp(\text{logr3})$. Then the model parameters can be described as follows:

- The parameters that are associated with the autoregression ζ_t : the damping factor $\rho = \frac{\exp(\text{rhoParm})-1}{\exp(\text{rhoParm})+1}$, the variance of the disturbance term $= a^2\sigma^2$, and the variance of the initial state $= a^2\sigma^2/(1 - \rho^2)$
- The parameters that are associated with the integrated random walk trend: the variance of the disturbance term in the slope equation $= \sigma^2$
- The variance of the observation errors for GISS $= a^2r_1^2\sigma^2$
- The variance of the observation errors for UAH $= a^2r_3^2\sigma^2$
- The variance of the observation errors for CRU is taken to be time-varying with the following form: for $t \leq \text{nobs}$,

$$\sigma_{2,t}^2 = a^2\sigma^2 \exp(2b + 2c \ t/\text{nobs})$$

where $\text{nobs} = 1,945$ (the number of observations in the unappended data set). For $t > 1,945$, it is fixed at its last value: $\sigma_{2,t}^2 = a^2\sigma^2 \exp(2b + 2c)$.

The following DATA step adds an observation index, *tindex*, to *Temp*, which is used in the CSSM procedure to define the time-varying observation error variance for CRU:

```
data mylib.temp;
  set temp;
  tindex = _n_;
run;
```

The following statements fit the preceding model to the *Temp* data:

```
ods output RegressionEstimates=regEst;
proc cssm data=mylib.Temp;
  id date interval=month;
  parms loga1 logr1 logr3 logsigma / upper=50;
```

```

parms b=0 c=0 / upper=50;
parms rhoParm;
rho = (exp(rhoParm)-1)/(exp(rhoParm)+1);
sigmaSq = exp(2*logsigma);
initSigmaSq = sigmaSq/(1-rho*rho);
a1 = exp(loga1);
a1Sq = a1*a1;
r1sq = exp(2*logr1);
r3sq = exp(2*logr3);
giss_var = a1Sq*r1sq*sigmaSq;
nobs=1945;
if tindex <= nobs then
    cru_var = a1Sq*exp(2*b + 2*c*tindex/nobs)*sigmaSq;
else cru_var = a1Sq*exp(2*b + 2*c)*sigmaSq;
uah_var = a1Sq*r3sq*sigmaSq;
UAH_Intercept=1.0;
CRU_Intercept=1.0;
trend level(11) variance=0 slopevar=sigmaSq;

comp auto_common = auto*(a1);
state wn(3) type=wn cov(d)=(giss_var cru_var uah_var);
comp wn_giss = wn[1];
comp wn_cru = wn[2];
comp wn_uah = wn[3];
model GISS = level auto_common wn_giss;
model CRU = CRU_Intercept level auto_common wn_cru;
model UAH = UAH_Intercept level auto_common wn_uah;
comp slope = level_state_*(0 1);
output out=mylib.For pdv press;
run;

```

Output 14.12.2 shows the estimated intercepts $\hat{\beta}_{cru}$ and $\hat{\beta}_{uah}$. As expected, they are quite close (see the scatter plots of CRU and UAH in Output 14.12.1).

Output 14.12.2 Estimated Intercepts for CRU and UAH

Regression Parameter Estimates					
Response	Regressor	Estimate	Standard		
			Error	t Value	Pr > t
CRU	CRU_Intercept	-4.0944	0.0036	-1139.0	<.0001
UAH	UAH_Intercept	-4.4756	0.0067	-666.54	<.0001

The estimates of the basic parameters that underlie the model parameters are shown in Output 14.12.3.

Output 14.12.3 Estimates of Basic Model Parameters

Estimates of Named Parameters			
Parameter	Estimate	Standard	
		Error	t Value
loga1	7.7763	0.3906	19.91
logr1	-1.0049	0.0884	-11.36
logr3	-0.2304	0.0453	-5.09
logsigma	-9.6386	0.3893	-24.76
b	0.7373	0.0502	14.69
c	-1.4025	0.0690	-20.34
rhoParm	1.4294	0.0766	18.66

The following DATA steps add two variables ($CRU_ADJ = CRU - \hat{\beta}_{cru}$ and $UAH_ADJ = UAH - \hat{\beta}_{uah}$) to the output data set mylib.For. These adjusted versions of CRU and UAH have the same mean level as GISS—estimated μ_t .

```
data _NULL_;
  set regEst;
  if _n_ = 1 then call symput('intercept1',trim(left(estimate)));
  else call symput('intercept2',trim(left(estimate)));
run;
data for;
  set mylib.For;
  cru_adj = cru - &intercept1;
  uah_adj = uah - &intercept2;
run;
```

The following statements produce a graph that contains four plots: scatter plots of GISS, CRU_ADJ, and UAH_ADJ and a series plot of the estimated μ_t .

```
proc sgplot data=For;
  where date < '01feb2021'd;
  title "Fitted Trend for the Temp Series (Up to Year 2020) ";
  title2 "(CRU and UAH Adjusted by Their Estimated Intercepts) ";
  scatter x=date y=cru_adj / LEGENDLABEL="Adjusted CRU"
    MARKERATTRS=GraphData1(symbol=star size=3);
  scatter x=date y=uah_adj / LEGENDLABEL="Adjusted UAH"
    MARKERATTRS=GraphData2(symbol=plus size=3);
  scatter x=date y=giss /
    MARKERATTRS=GraphData3(symbol=triangle size=3);
  series x=date y=smoothed_level / MARKERATTRS=GraphData4;
run;
```

Output 14.12.4 shows the resulting graph. It shows that the estimated mean level μ_t tracks the observed data quite well.

Output 14.12.4 Fitted Trend μ_t 

The following statements produce the time series plot of the estimated μ_t along with the 95% confidence band:

```
proc sgplot data=For;
  title "Temperature Projections for the Next 100 Years";
  band x=date lower=smoothed_lower_level upper=smoothed_upper_level;
  series x=date y=smoothed_level;
  refline '01feb2012'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
run;
```

Output 14.12.5 shows the resulting graph.

Output 14.12.5 Long-Term Forecasts of μ_t 

The following statements produce a similar graph for the estimated slope of μ_t :

```
proc sgplot data=For;
  where date <= '01feb2031'd;
  title "The Monthly Rate of Temperature Change (Up to Year 2030)";
  band x=date lower=smoothed_lower_slope upper=smoothed_upper_slope;
  series x=date y=smoothed_slope;
  refline '01feb2012'd / axis=x lineattrs=(pattern=shortdash)
    LEGENDLABEL= "Start of Multistep Forecasts"
    name="Forecast Reference Line";
  refline 0 / axis=y lineattrs=(pattern=dash);
run;
```

Output 14.12.6 shows the resulting plot of the estimated slope of μ_t .

Output 14.12.6 Forecasts of the Slope of μ_t 

Based on the preceding analysis (see the plots of μ_t and its slope in [Output 14.12.5](#) and [Output 14.12.6](#)), it appears that there has been statistically significant warming over the last 10 years, but the warming does not appear to be accelerating.

Example 14.13: Bivariate Model for Sales of Mink and Muskrat Furs

This example considers a bivariate time series of logarithms of the annual sales of mink and muskrat furs by the Hudson's Bay Company for the years 1850–1911. These data have been analyzed previously by many authors, including Chan and Wallis (1978); Harvey (1989); Reinsel (1997). There is known to be a predator-prey relationship between the mink and muskrat species: minks are principal predators of muskrats. Previous analyses for these data generally conclude the following:

- An increase in the muskrat population is followed by an increase in the mink population a year later, and an increase in the mink population is followed by a decrease in the muskrat population a year later.
- Because muskrats are not the only item in the mink diet and because both mink and muskrat populations are affected by many other factors, the model must include additional terms to explain the year-to-year variation.

The analysis in this example, which loosely follows the discussion in Harvey (1989, chap. 8, sec. 8), also leads to similar conclusions. It begins by taking Harvey's model 8.8.8 (a and b), with autoregressive order one, as the starting model—that is, it assumes that the bivariate (mink, muskrat) process $\mathbf{Y}_t$ satisfies the following relationship:

$$\begin{aligned}\boldsymbol{\mu}_t &= \boldsymbol{\mu}_{t-1} + \boldsymbol{\beta} + \mathbf{v}_t \\ \mathbf{Y}_t &= \boldsymbol{\mu}_t + \boldsymbol{\Phi}\mathbf{Y}_{t-1} + \boldsymbol{\xi}_t\end{aligned}$$

This model postulates that $\mathbf{Y}_t$ can be expressed as a sum of three terms: $\boldsymbol{\mu}_t$, a bivariate trend that is modeled as a random walk with drift $\boldsymbol{\beta}$; $\boldsymbol{\Phi}\mathbf{Y}_{t-1}$, an AR(1) correction; and $\boldsymbol{\xi}_t$, a bivariate Gaussian white noise disturbance. It is assumed that the AR coefficient matrix $\boldsymbol{\Phi}$ is stable (that is, its eigenvalues are less than 1 in magnitude) and that the bivariate disturbances $\mathbf{v}_t$ (white noise associated with $\boldsymbol{\mu}_t$) and $\boldsymbol{\xi}_t$ are mutually independent.

The following statements load the furs data into the table mylib.Cigar:

```
/* Load data into mylib */
data mylib.furs;
  set furs;
run;
```

The following statements show how you can specify this model in the CSSM procedure:

```
proc cssm data=mylib.furs plots=residual;

  /* Specify the ID variable */
  id year interval=year;

  /* Define parameters */
  parms rho1 rho2/ lower=-0.9999 upper=0.9999;
  parms msd1 msd2 esd1 esd2 / lower=1.e-6;

  /* Specify the terms with lagged response variables */
  deplag LagsForMink(LogMink) LogMink(lags=1) LogMusk(lags=1);
  deplag LagsForMusk(LogMusk) LogMink(lags=1) LogMusk(lags=1);

  /* Specify the bivariate trend */
  array rwQ{2,2};
  rwQ[1,1] = msd1*msd1; rwQ[1,2] = msd1*msd2*rho1;
  rwQ[2,1] = rwQ[1,2]; rwQ[2,2]=msd2*msd2;
  state alpha(2) type=RW W(I) cov(g)=(rwQ);
  comp minkLevel = alpha[1];
  comp muskLevel = alpha[2];

  /* Specify the bivariate white noise */
  array wnQ{2,2};
  wnQ[1,1] = esd1*esd1; wnQ[1,2] = esd1*esd2*rho2;
  wnQ[2,1] = wnQ[1,2]; wnQ[2,2]=esd2*esd2;
  state error(2) type=WN cov(g)=(wnQ);
  comp minkWn = error[1];
  comp muskWn = error[2];

  /* Specify the observation equation */
  model LogMink = LagsForMink minkLevel minkWn;
```

```

model LogMusk = LagsForMusk muskLevel muskWn;

/* Specify an output data set to store component estimates */
output out=mylib.salesFor press;

run;

```

The different parts of the program are explained as follows:

- The PARMs statements define parameters that are used to form the elements of Σ_1 (the covariance of $\mathbf{v}_t$, the disturbance term in the bivariate level equation) and Σ_2 (the covariance of ξ_t , which is the bivariate white noise). Σ_1 is parameterized as (msd1*msd1 msd1*msd2*rho1; msd1*msd2*rho1 msd2*msd2). Σ_2 is similarly parameterized by using esd1, esd2, and rho2. In addition to ensuring that Σ_1 and Σ_2 are positive semidefinite, it turns out that this parameterization leads to an interpretable model at the end.
- The DEPLAG statements help define the terms that are associated with $\Phi \mathbf{Y}_{t-1}$.
- The remaining statements are self-explanatory.

Output 14.13.1 shows the estimate of the drift vector β in the equation of μ_t ($\mu_t = \mu_{t-1} + \beta + \mathbf{v}_t$).

Output 14.13.1 Estimate of the Drift Vector β

Estimate of the State Equation Regression Vector					
State	Element Index	Estimate	Standard Error	t Value	Pr > t
alpha	1	-0.0008	0.0323	-0.03	0.9798
alpha	2	0.0060	0.0258	0.23	0.8175

Clearly, both elements of β are statistically insignificant, and the μ_t equation can be simplified as $\mu_t = \mu_{t-1} + \mathbf{v}_t$. Next, Output 14.13.2 shows the estimates of the elements of Σ_1 , and Σ_2 , and Output 14.13.3 shows the estimates of the lag coefficients.

Output 14.13.2 Estimates of Σ_1 , and Σ_2

Estimates of Named Parameters			
Parameter	Estimate	Standard Error	t Value
rho1	0.8310	0.1377	6.03
rho2	-0.9999	1.6555	-0.60
msd1	0.2500	0.0354	7.06
msd2	0.1991	0.0592	3.36
esd1	0.0662	0.0597	1.11
esd2	0.1344	0.0527	2.55

Output 14.13.3 Estimates of Lag Coefficients (Elements of Φ)

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
LagsForMink	Lag Coefficient Of LogMink	Lag[1]	-0.0011	0.1730	-0.01
LagsForMink	Lag Coefficient Of LogMusk	Lag[1]	0.3349	0.1369	2.45
LagsForMusk	Lag Coefficient Of LogMink	Lag[1]	-0.9905	0.1419	-6.98
LagsForMusk	Lag Coefficient Of LogMusk	Lag[1]	0.6570	0.1208	5.44

The main points of the output can be summarized as follows:

- phi11, the first element of Φ , which relates the current value of LogMink with its lagged value, is statistically insignificant. That is, lagged LogMink term could be dropped from the model equation for LogMink.
- rho2, the correlation coefficient between the elements of ξ_t —the bivariate noise vector in the equation $Y_t = \mu_t + \Phi Y_{t-1} + \xi_t$ —is very near its lower boundary of -1 (in such cases the standard error of the parameter estimate is not reliable). This implies that the two elements of ξ_t are perfectly negatively correlated.

Taken together, these observations suggest the reduced model

$$\mu_t = \mu_{t-1} + v_t$$

$$Y_t = \mu_t + \Phi Y_{t-1} + \xi_t$$

where $\Phi = (0 \quad \phi_{12}; \phi_{21} \quad \phi_{22})$ and $\text{Cov}(\xi_t) = \Sigma_2$ is parameterized as (**esd1*esd1 -esd1*esd2; -esd1*esd2 esd2*esd2**). The program that produces the reduced model is a simple modification of the preceding program and is not shown.

Output 14.13.4 Estimates of Σ_1 , and Σ_2 (Reduced Model)

Estimates of Named Parameters			
Parameter	Estimate	Standard Error	t Value
rho1	0.8526	0.0978	8.71
msd1	0.2472	0.0282	8.78
msd2	0.1955	0.0365	5.36
esd1	0.0679	0.0385	1.76
esd2	0.1372	0.0328	4.18

Output 14.13.5 Estimates of Lag Coefficients (elements of Φ) (Reduced Model)

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
LagsForMink	Lag Coefficient Of LogMusk	Lag[1]	0.3303	0.0986	3.35
LagsForMusk	Lag Coefficient Of LogMink	Lag[1]	-0.9973	0.1168	-8.54
LagsForMusk	Lag Coefficient Of LogMusk	Lag[1]	0.6680	0.1003	6.66

The tables in [Output 14.13.4](#) and [Output 14.13.5](#) show the new parameter estimates. By examining the parameter estimates, you can easily see that this model supports the general conclusions mentioned at the start of this example. In particular, note the following:

- $\hat{\phi}_{12} = 0.33$ implies that this year's mink abundance is positively correlated with last year's muskrat abundance.
- $\hat{\phi}_{21} = -0.99$ and $\hat{\phi}_{22} = 0.66$ imply that this year's muskrat abundance is negatively correlated with last year's mink abundance and positively correlated with last year's muskrat abundance.
- Even though the parameters were not restricted to ensure stability, the estimated Φ turns out to be stable with a pair of complex eigenvalues, $0.317 \pm i 0.473$, and a modulus of 0.570 (these calculations are done separately by using the IML procedure).
- The fact that elements of ξ_t are perfectly negatively correlated further supports the predator-prey relationship.

Finally, [Output 14.13.6](#) shows the plots of one-step-ahead and post-sample forecasts for LogMink and LogMusk, and [Output 14.13.7](#) shows the plot of the smoothed (full-sample) estimate of the first element of μ_t : LogMink Trend.

Output 14.13.6 Forecasts for Mink and Muskrat Fur Sales in Logarithms

Output 14.13.7 Smoothed Estimate of LogMink Trend

Example 14.14: A Factor Model for Now-Casting the US Economy

A well-known business conditions index, the Aruoba-Diebold-Scotti (ADS) business conditions index, is designed to track real business conditions at high frequency (for more information about this index, see <http://www.philadelphiafed.org/research-and-data/real-time-center/business-conditions-index/>). Its underlying (seasonally adjusted) economic indicators (weekly initial jobless claims, monthly payroll employment, industrial production, personal income less transfer payments, manufacturing and trade sales, and quarterly real GDP) blend high- and low-frequency information with stock and flow data. The ADS index is based on a rather elaborate state space model that takes into account the stock and flow nature of the underlying economic indicators. To simplify the illustration, this example uses the same economic indicators to develop a similar index by using a simpler factor model. You can also use PROC CSSM to carry out the more elaborate modeling that underlies the ADS index. All these economic indicators are freely available from the Federal Reserve Economic Data (FRED). You can access these data by using the SASEFRED interface engine; see Chapter 48, “SASEFRED Interface Engine” (*SAS/ETS User’s Guide*). The names of analysis variables and the relevant information that is needed for using the SASEFRED engine to obtain these data are shown in Table 14.11. All variables are transformed versions of the original series: all, except `l_icsa`, are both logged and differenced; `l_icsa` is only logged. The input data set for the

analysis, named *econ*, is formed by merging these six series of different frequencies. This merging is done by treating them as daily series that have missing values on the days when the series values are not available—for example, *ld_pinc* is nonmissing only for the first day of the month. The *econ* data set contains one more variable, *recession*, which is an indicator variable for the recessionary periods. This time series is an interpretation of the US Business Cycle Expansions and Contractions data that are provided by the National Bureau of Economic Research (NBER) at <http://www.nber.org/cycles/cyclesmain.html> (also see <http://research.stlouisfed.org/fred2/series/USRECDM>). The variable *recession* is not used in modeling. It is used later to demonstrate the adequacy of the activity index that is created in this example.

Table 14.11 Analysis Variables and Their FRED IDs

Name	FRED ID	Frequency	Description
<i>ld_payemp</i>	PAYEMS	Monthly	Payroll employment
<i>ld_pinc</i>	W875RX1	Monthly	Real personal income excluding current transfer receipts
<i>ld_mnfctr</i>	CMRMTSPL	Monthly	Real manufacturing and trade industries sales
<i>ld_indpro</i>	INDPRO	Monthly	Industrial production index
<i>ld_gdp</i>	GDPC1	Quarterly	Real GDP
<i>l_icsa</i>	ICSA	Weekly	Initial jobless claims

For easier model description, the variables *ld_payemp* to *ld_gdp* are also denoted as y_{1t} to y_{5t} , and the variable *l_icsa* is denoted as y_{6t} . Using this notation, the following model is postulated for the six daily time series:

$$y_{it} = \text{intercept}_i + \beta_i * \text{irw}_t + \epsilon_{it} \quad 1 \leq i \leq 5$$

$$y_{6t} = \mu_t + \beta_6 * \text{irw}_t + \epsilon_{6t}$$

A justification for this model is based on the following observations:

- The five time series y_{1t} to y_{5t} are logged and differenced versions of the underlying economic variables. Their plots (not shown here) show them to be hovering around a constant level, with some periods of deviation from this level. The plot of the sixth series, y_{6t} , which is logged but not differenced, shows a pronounced nonstationary pattern.
- All these series can be considered as proxies, possibly noisy, for the national economic activity. It is therefore reasonable to assume that a model for each of them will contain a common component, appropriately weighted, that is associated with the economic activity. In the current model this common component, named irw_t , is modeled as an integrated random walk. For y_{1t} to y_{5t} , the only other terms in the model are the respective intercepts, intercept_i , and the random disturbances, ϵ_{it} . Because y_{6t} shows a pronounced nonstationary pattern, its model has a time-varying level, μ_t , which is also modeled as an integrated random walk. For identifiability purposes, the initial condition for irw_t is taken to be 0. For the same reason, β_1 , the coefficient of irw_t in the model for y_{1t} is taken to be 1.
- The underlying economic variables of the five time series y_{1t} to y_{5t} are positively correlated with the economic activity—for example, payroll employment is expected to increase with increased economic activity. On the other hand, y_{6t} , which is associated with the initial jobless claims, is negatively correlated with the economic activity. This means that, with β_1 taken to be 1, the estimates of

$\beta_2, \dots, \beta_5$ are expected to be positive and the estimate of β_6 is expected to be negative. In the factor modeling terminology, irw_t is called a factor and $\beta_1, \dots, \beta_6$ are called the associated factor loadings.

The following statements load the econ data into the table mylib.econ:

```
/* Load data into mylib */
data mylib.econ;
  set econ;
run;
```

The following statements show you how to specify this model in the CSSM procedure:

```
ods output NamedParameterEstimates = named;
proc cssm data=mylib.econ; * opt(tech=activeset);
  id date interval=day;
  parms beta2-beta6;

eval IndexSlope = 1000*slope;
/*--just so recession is output to the output data set--*/
rec = recession;
output out=mylib.forecast1 press pdv;
run;

```

A few comments about the program:

- If the model and data are in reasonable accord, the default likelihood optimization settings work in most situations. However, in some cases the likelihood optimization process needs additional customization. Some experimentation with alternative optimization techniques and different parameterization of the model parameters can help. This example turns out to be one such case. The optimization technique **ACTIVESET** (`opt (tech=activeset)`) works better for WINDOWS and a few other platforms, whereas the default optimization technique works better for the AIX platform. In addition, the variances of all the disturbance terms in the model are parameterized in the exponential scale.
- The two-dimensional state that is associated with irw_t is named `latent`, and irw_t (the first element of `latent`) itself is named `c1`. Note that the second element of `latent` corresponds to the slope of irw_t . The components `c2` to `c6` correspond to $\beta_i * \text{irw}_t$ for $2 \leq i \leq 6$.
- The desired business index, named `index`, is a scaled version of irw_t (`eval Index = 1000*c1;`). This scaling is done purely for ease of display—the scaled values turn out to be in the range of -6.0 to 5.0 . Another component, named `IndexSlope`, contains the slope of `index`, which is also a quantity of interest.

Output 14.14.1 Estimated Factor Loadings

The Estimated Loadings

Parameter	Estimate	StdErr	tValue
beta2	1.1457	0.1276	8.98
beta3	1.9605	0.2390	8.20
beta4	2.4816	0.1646	15.08
beta5	3.2715	0.2653	12.33
beta6	-96.4457	9.6133	-10.03

Output 14.14.1 shows the estimated factor loadings. They are statistically significant and their signs are consistent.

Output 14.14.2 The Estimate of Economic Activity Index

Output 14.14.2 shows the plot of the smoothed index. Note that it coheres quite well with the NBER recessionary periods. In Aruoba, Diebold, and Scotti (2009, sec. 4.4) the features of an earlier version of the ADS index are discussed in detail. Similar comments apply to this indicator also.

Output 14.14.3 Estimated Slope of the Economic Activity Index

Finally, [Output 14.14.3](#) shows the plot of the slope of the index, which gives an idea of the direction of the economic activity.

Example 14.15: Longitudinal Data Analysis of Lung Function Data

The data for this example, which consist of 209 measurements of the lung function of an asthma patient, are analyzed in Wang (2013). The time series is measured mostly at two-hour time intervals but with irregular gaps. Wang (2013) fit a fourth-order continuous-time autoregressive model, CAR(4), to these data. The analysis results in a decomposition of the observed time series in three components:

- a slowly varying trend pattern, which appears to have a slight downward drift
- a diurnal component—a periodic pattern with a period of 24 hours
- a residual component

As shown in Wang (2013), the continuous-time autoregressive models can be formulated as state space models. However, in general, the form of such SSMs is quite complex. Consequently, specifying such a

model by using the current CSSM procedure syntax is impractical. On the other hand, you can analyze these types of longitudinal data by using continuous-time structural models, which are easy to specify in the SSM procedure. In this example, the lung function measurements, y , are modeled as

$$y_t = \text{intercept} + \beta * t + \zeta_t + \epsilon_t$$

where $(\text{intercept} + \beta * t)$ is a simple linear time trend, ζ_t is a continuous-time stochastic cycle, and ϵ_t is a Gaussian white noise sequence. Replacing the linear time trend with a more general time trend, such as a spline smoother, does not seem to change the fit, because the estimated smoothing spline turns out to be almost perfectly linear.

The following statements load the asth data into the table mylib.asth:

```
/* Load data into mylib */
data mylib.asth;
  set asth;
run;
```

The following statements show you how to specify this model in the CSSM procedure:

```
proc cssm data=mylib.asth;
  id time;
  state s1(1) type=cycle(CT) cov(g);
  comp c1 = s1[1];
  intercept = 1;
  irregular wn;
  model y= intercept time c1 wn;
  output out=mylib.for1 press;
  eval pattern=intercept+time+c1;
run;
```

The continuous-time stochastic cycle, named $c1$, is defined by a pair of STATE and COMPONENT statements. The STATE statement defines $s1$ as a state subsection that is associated with a univariate, continuous-time cycle (signified by the use of **type=cycle(CT)**). The COMPONENT statement defines $c1$ as its first element.

Output 14.15.1 Linear Time Trend: Estimates of Intercept and Slope

Regression Parameter Estimates					
Response	Regressor	Estimate	Standard		
			Error	t Value	Pr > t
y	intercept	502.1637	3.5047	143.28	<.0001
y	time	-0.0201	0.0092	-2.19	0.0286

Output 14.15.1 shows the estimated intercept and slope of the time trend. The estimated slope (only marginally significant) is negative, which is consistent with the overall downward drift.

Output 14.15.2 Estimated Stochastic Cycle: ζ_t 

Output 14.15.2 shows the plot of the estimated cycle component, which has a period of 24.78 hours and a damping factor of 0.97. That is, it is a nearly persistent diurnal cycle.

Output 14.15.3 Estimated Pattern: Intercept + $\beta * t + \zeta_t$ 

Output 14.15.3 shows the fit of the de-noised y values (intercept + $\beta * t + \zeta_t$). To reduce the clutter, only the second half of the data are plotted. The fit appears to be quite reasonable.

Example 14.16: Estimating Monthly GDP by Temporal Distribution

This example is based on a case study described in Pelagatti (2015, chap. 9, Example 9.2). The case study shows how you can estimate the monthly GDP (gross domestic product) for the United States by temporally distributing the quarterly GDP time series, which is readily available. The temporal distribution process is based on a bivariate model that relates two variables, the quarterly GDP and the monthly industrial production index (both for the United States). Assuming that t denotes the monthly time index, $indp_t$ denotes the monthly industrial production index series, and gdp_t denotes the quarterly GDP series that is organized as a monthly series (by setting the GDP numbers to missing for the months when they are not published), the case

study uses the following model,

$$\begin{aligned} \text{indp}_t &= \mu_{1,t} + \psi_{1,t} + \epsilon_{1,t} \\ \text{gdp}_t^\dagger &= \mu_{2,t} + \psi_{2,t} + \epsilon_{2,t} \\ \text{gdp}_t &= \text{gdp}_t^\dagger + \text{gdp}_{t-1}^\dagger + \text{gdp}_{t-2}^\dagger \end{aligned}$$

where

- $\text{gdp}_t^\dagger$ is the unobserved monthly GDP series (which is to be estimated)
- $\boldsymbol{\mu}_t = (\mu_{1,t} \ \mu_{2,t})$ is a bivariate trend component that follows an integrated random walk
- $\boldsymbol{\psi}_t = (\psi_{1,t} \ \psi_{2,t})$ is a bivariate cycle component
- $\boldsymbol{\epsilon}_t = (\epsilon_{1,t} \ \epsilon_{2,t})$ is a bivariate white noise component

As explained in the section “[Temporal Distribution](#)” on page 790, it is easy to fit this model by using the CSSM procedure. As a first step, a data set, `Usec`, is created that organizes the monthly industrial production index and the quarterly GDP as monthly series. Specifically, `Usec` contains four variables: `date` dates the observations, `indpro` contains the monthly industrial production index, `gdp` contains the quarterly GDP, and `startQ` is a dummy variable that indicates the start of the quarter. This data set is essentially the same as the one that is used in the case study, except that, to improve the computational stability, `gdp` is scaled by 100. This data set has one peculiarity that is not mentioned in the case study: the GDP reporting pattern appears to have changed a few times over the years (October 1969, May 1992, and December 2014). The dummy variable, `startQ`, which indicates the start of the aggregation interval, is appropriately modified to take these changes into account. [Output 14.16.1](#) shows the first few rows of `Usec`.

Output 14.16.1 First Few Rows of `Usec`

date	startQ	gdp	indpro
01JAN47	1	.	13.6351
01FEB47	0	.	13.7156
01MAR47	0	19.3447	13.7962
01APR47	1	.	13.6888
01MAY47	0	.	13.7425
01JUN47	0	19.3228	13.7425
01JUL47	1	.	13.6619
01AUG47	0	.	13.7425

The following statements load the `useco` data into the table `mylib.useco`:

```
/* Load data into mylib */
data mylib.useco;
  set useco;
run;
```

The following statements show you how to specify the bivariate model for `indpro` and `gdp`:

```

proc cssm data=mylib.useco opt(maxiter=100);
  id date interval=month;
  /* Bivariate integrated random walk */
  state irwState(2) type=ll(slopecov(g));
  comp irwInd = irwState[1];
  comp irwGdp = irwState[2];
  /* Bivariate cycle */
  state cycle(2) type=cycle cov(g);
  comp cycInd = cycle[1];
  comp cycGdp = cycle[2];
  /* Bivariate white noise */
  state noise(2) type=wn cov(g);
  comp noiseInd = noise[1];
  comp noiseGdp = noise[2];
  /* Observation equations */
  model indpro = irwInd cycInd noiseInd;
  model gdp = irwGdp cycGdp noiseGdp / distribute(start=startQ);
  /* Components for output */
  eval trendCycGdp = irwGdp + cycGdp;
  eval trendCycInd = irwInd + cycInd;
  eval monthlyGdp = irwGdp + cycGdp + noiseGdp;
  /* Output data set */
  output out=mylib.forGdp pdv press;
run;

```

Here are a few comments about this program:

- The first STATE statement specifies `irwState` as a bivariate trend that follows an integrated random walk (which is a local linear trend without the disturbance term in the level equation); `irwState` corresponds to μ_t . The trend components in the models for `indpro` and `gdp` are specified in the two COMP statements that follow: `irwInd` and `irwGdp` correspond to $\mu_{1,t}$ and $\mu_{2,t}$, respectively.
- Similarly, the second STATE statement and the two COMP statements that follow it define `cycInd` and `cycGdp` as the two cycle components ($\psi_{1,t}$ and $\psi_{2,t}$) in the model.
- The noise components, `noiseInd` and `noiseGdp`, which correspond to $\epsilon_{1,t}$ and $\epsilon_{2,t}$, respectively, are also defined in the same way.
- The MODEL statement for `indpro` corresponds to the equation $indp_t = \mu_{1,t} + \psi_{1,t} + \epsilon_{1,t}$. On the other hand, the DISTRIBUTE(START=*startQ*) option in the MODEL statement of `gdp` causes `gdp` to be modeled as an aggregated version of the unobserved monthly GDP series ($gdp_t^\dagger$):

$$\begin{aligned}
 gdp_t^\dagger &= \mu_{2,t} + \psi_{2,t} + \epsilon_{2,t} \\
 gdp_t &= gdp_t^\dagger + gdp_{t-1}^\dagger + gdp_{t-2}^\dagger
 \end{aligned}$$

- After the model specification is complete, EVAL statements are used to define some useful linear combinations of the components that are part of the model specification—for example, `monthlyGdp` (which is defined as a sum of `irwGdp`, `cycGdp`, and `noiseGdp`) corresponds to the unobserved monthly GDP ($gdp_t^\dagger$). The CSSM procedure outputs the estimates of these components to the data set that is specified in the OUT= option in the OUTPUT statement.

The parameter estimates in [Output 14.16.2](#) are similar to (but not the same as) the parameter estimates reported in the case study. In particular, the estimates of the parameters of the cycle component—for example, the damping factor ($\text{Rho} = 0.99228$) and the period (293.32178)—are reasonably close.

Output 14.16.2 Estimated Model Parameters

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
irwState	Slope Disturbance Covariance	RootCov[1, 1]	0.1065	0.0136	7.85
irwState	Slope Disturbance Covariance	RootCov[2, 1]	0.0206	0.0029	7.05
irwState	Slope Disturbance Covariance	RootCov[2, 2]	0.0013	0.0005	2.52
cycle	Damping Factor	Rho	0.9923	0.0046	215.80
cycle	Cycle Period	Period	293.3218	94.2697	3.11

[Output 14.16.3](#) shows the plot of the estimated monthly GDP, and [Output 14.16.4](#) shows the plot of the estimate of monthly trend-cycle estimate ($\mu_{2,t} + \psi_{2,t}$) for GDP.

Output 14.16.3 Estimate of Monthly GDP

Output 14.16.4 Smoothed Trend-Cycle Component of Monthly GDP (1950 to 1960)

Example 14.17: Temporal Aggregation-Based Triannual Nile River Level

This example illustrates how you can do model-based temporal aggregation of a response variable. The following DATA step creates a data set, Nile, by using a well-known data set that contains annual recordings of the Nile water level measured between the years 1871 and 1970. The Nile water level is clearly a stock variable, and temporal aggregation of such variables is usually meaningless. However, for illustration purposes, assume that you are interested in forecasting triannual totals of the water level.

```
data Nile;
  input level @@;
  year = intnx( 'year', '1jan1871'd, _n_-1 );
  format year year4.;
  startAggr = (mod(_n_, 3) = 1);
datalines;
1120 1160 963 1210 1160 1160 813 1230 1370 1140
995 935 1110 994 1020 960 1180 799 958 1140
1100 1210 1150 1250 1260 1220 1030 1100 774 840
874 694 940 833 701 916 692 1020 1050 969
```

```

831    726    456    824    702    1120    1100    832    764    821
768    845    864    862    698    845    744    796    1040    759
781    865    845    944    984    897    822    1010    771    676
649    846    812    742    801    1040    860    874    848    890
744    749    838    1050    918    986    797    923    975    815
1020    906    901    1170    912    746    919    718    714    740
. . . . .
;

```

The following statements load the Nile data into the table mylib.Nile:

```

/* Load data into mylib */
data mylib.Nile;
    set Nile;
run;

```

The Nile data set contains three variables: year indicates the observation year, level contains the yearly water level, and startAggr is a dummy variable that indicates the start of the triannual aggregation intervals. It is known that for the time span of the observations, the yearly water levels can be reasonably modeled as a sum of a random walk trend, a level shift in the year 1899, and the observation error. The following statements show you how to obtain forecasts of the triannual water level that are consistent with the model postulated for the yearly water levels:

```

proc cssm data=mylib.Nile;
    id year interval=year;
    shift1899 = ( year >= '1jan1899'd );
    trend rw(rw);
    irregular wn;
    model level = shift1899 RW wn / aggregate(start=startAggr);
    output out=mylib.nileOut;
quit;

```

As a result of running this program, you get the usual output that is associated with fitting the specified model to the yearly water level. In addition (as explained in the section “[Temporal Aggregation](#)” on page 792), the AGGREGATE option in the MODEL statement causes the estimation and printing of triannual aggregates of the water level. [Output 14.17.1](#) shows the last few rows of this output. When the summands—the response values—in the aggregation are known, the aggregation can be done without error; that is, the standard error of the estimation is zero. However, when at least one summand in the aggregate is missing, the standard error of estimation is nonzero.

Output 14.17.1 Triannual Aggregate Values of the Nile Water Levels (Partial Output)

Time	Response	Start_Flag	Aggregate	StdErr	Lower	Upper
1967	919	1	919	0.0000	919.0	919
1968	718	0	1637	0.0000	1637.0	1637
1969	714	0	2351	0.0000	2351.0	2351
1970	740	1	740	0.0000	740.0	740
1971	.	0	1590	128.4764	1338.2	1842
1972	.	0	2440	182.9334	2081.4	2798
1973	.	1	850	128.4764	598.2	1102
1974	.	0	1700	182.9334	1341.4	2058
1975	.	0	2550	225.5554	2107.8	2992
1976	.	1	850	128.4764	598.2	1102
1977	.	0	1700	182.9334	1341.4	2058

Example 14.18: Invariance of the Marginal Likelihood under Linear Rescaling of the Diffuse Effects

Consider the following alternate but equivalent specifications of a trend-plus-seasonal model (monthly seasonality):

$$y_t = \mu_t + \psi_t + \epsilon_t \quad \text{Spec1}$$

$$y_t = \mu_t + m_{1,t} + \cdots + m_{11,t} + \epsilon_t \quad \text{Spec2}$$

Here the trend (μ_t , a random walk with drift) and the irregular component (ϵ_t , white noise) are the same in both the specifications. However, the seasonal component is specified differently: in Spec1 the seasonality is modeled as a deterministic trigonometric seasonal component (ψ_t) whereas in Spec2 it is modeled using the seasonal dummies ($m_1 \cdots m_{11}$). Spec1 and Spec2 are statistically equivalent models from the perspective of the data generation process. This example uses these two specifications to demonstrate a useful invariance property of the marginal and profile likelihoods, which is described in the section “[Likelihood Computation and Model-Fitting Phase](#)” on page 769. The airline passenger series, given as Series G in Box and Jenkins (1976), is used to illustrate the computations. The following DATA step prepares the log-transformed passenger series and the seasonal dummies that are needed for this example:

```
data mylib.seriesG;
  set sashelp.air;
  logair = log(air);
  array m{11} m1-m11;
  do i=1 to 11;
    m[i] = (month(date)=i);
  end;
run;
```

The following statements fit the two models to the log-transformed passenger series. The first PROC CSSM call fits Spec1, and the second call fits Spec2.

```

proc cssm data=mylib.seriesG plots=none like=marginal;
  id date interval=month;
  trend rwDrift(11) slopevar=0;
  irregular wn;
  state trigState(1) type=season(length=12);
  comp season = trigState[1];
  model logair = rwDrift season wn;
run;

proc cssm data=mylib.seriesG plots=none like=marginal;
  id date interval=month;
  trend rwDrift(11) slopevar=0;
  irregular wn;
  model logair = rwDrift m1-m11 wn;
run;

```

For these two models, the parameter estimates that are based on the diffuse likelihood (REML_D) and the marginal likelihood ((REML_M) coincide because the extra term in the marginal likelihood ($-\log(|S_{n,p_n}^*|)$) turns out to be independent of these parameters. Nevertheless, it is useful to use the LIKE=MARGINAL option in the PROC CSSM statement so that both the likelihood computation summary and the information criteria tables display the likelihood values and the information criteria for all three likelihoods—diffuse, marginal, and profile—at the estimated parameters. The parameter estimates for Spec1 and Spec2 are displayed in [Output 14.18.1](#) and [Output 14.18.2](#), respectively. As expected, the parameter estimates for the two specifications are the same because they are statistically equivalent models. The other aspects of the fit (such as model-based forecasts), which are not shown, also agree.

Output 14.18.1 Parameter Estimates For Spec1

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
rwDrift	LL Trend	Level Variance	0.0008	0.0002	3.49
wn	Irregular	Variance	0.0004	0.0001	2.60

Output 14.18.2 Parameter Estimates For Spec2

Model Parameter Estimates					
Component	Type	Parameter	Estimate	Standard Error	t Value
rwDrift	LL Trend	Level Variance	0.0008	0.0002	3.49
wn	Irregular	Variance	0.0004	0.0001	2.60

The fit summary tables shown in [Output 14.18.3](#) (for Spec1) and [Output 14.18.4](#) (for Spec2) show that the marginal and profile likelihoods (the last two lines in each table) for the two specifications also agree. However, you can see that the diffuse likelihood value for the two specifications differ (diffuse likelihood = 215.45 for Spec1 and diffuse likelihood = 226.89 for Spec2). This difference occurs because the diffuse likelihood is not invariant to the different (but equivalent) formulations of the seasonal effects. This also means that the information criteria that are based on the marginal and profile likelihoods, which are shown in [Output 14.18.5](#) (for Spec1) and [Output 14.18.6](#) (for Spec2), correctly conclude that the two specifications cannot be distinguished on the basis of these criteria, whereas the information criteria that are based on the

diffuse likelihood erroneously suggest that Spec1 is inferior to Spec2.

Output 14.18.3 Likelihood Computation Summary For Spec1

Likelihood Computation Summary	
Nonmissing Response Values Used	144
Estimated Parameters	2
Initialized Diffuse State Elements	13
Normalized Residual Sum of Squares	131.0000
Diffuse Log Likelihood	215.4522

BIC (lower is better)	-421.2	-456.7	-486.3
AICC (lower is better)	-426.8	-497.5	-491.9
HQIC (lower is better)	-424.6	-483.2	-489.7
CAIC (lower is better)	-419.2	-441.7	-484.3

Output 14.18.6 Information Criteria For Spec2

Information Criteria			
Statistic	Diffuse Likelihood	Profile Likelihood	Marginal Likelihood
AIC (lower is better)	-449.8	-501.3	-492.0
BIC (lower is better)	-444.0	-456.7	-486.3
AICC (lower is better)	-449.7	-497.5	-491.9
HQIC (lower is better)	-447.5	-483.2	-489.7
CAIC (lower is better)	-442.0	-441.7	-484.3

This example highlights the care that must be taken while doing model selection based on information criteria. It suggests that information criteria that are based on the marginal and profile likelihoods are preferred over

the information criteria that are based on diffuse likelihood.

Example 14.19: Scenario Analysis Using Scoring

In many data analyses, after you identify and fit a suitable state space model, you need to use the fitted model to predict the response series under different predictor scenarios in the future. You can easily accomplish this by using the scoring functionality that the **SCORE** statement provides. This example uses the data and the model discussed in the section “[Getting Started: CSSM Procedure](#)” on page 722 to demonstrate this type of scenario analysis. Recall that the data set, *Cigar*, contains information about yearly per capita cigarette sales for 46 geographic regions in the United States over the period 1963–1992. The variables *lsales*, *lprice*, *lndi*, and *lpimin* denote the per capita cigarette sales, price per pack of cigarettes, per capita disposable income, and minimum price in adjoining regions per pack of cigarettes, respectively (all in the natural log scale). The variable *year* contains the observation year, and the variable *region* contains an integer from 1 to 46 that serves as the unique identifier of the region. The goal of the analysis is to study the impact of the regressors on smoking behavior and to understand the changes in smoking patterns in different regions over those years. The following model for *lsales* is fitted:

$$\text{lsales}_{i,t} = \mu_{i,t} + \text{lprice} \beta_1 + \text{lndi} \beta_2 + \text{lpimin} \beta_3 + \epsilon_{i,t}$$

This example uses this model to predict *lsales* in the years 1993 and 1994 for three different settings of the predictors *lprice*, *lpimin*, and *lndi*. The first step in this type of scenario analysis is to create a score store in which the necessary context information is saved. The following statements specify and fit this model and also create the required score store:

```
proc cssm data=mylib.Cigar;
  id year interval=year;
  obsindex region;
  array RegionArray{46} region1-region46;
  do i=1 to 46;
    RegionArray[i] = (region=i);
  end;
  trend IrwTrend(11) cross(matchparm)=(RegionArray) levelvar=0;
  irregular wn;
  model lsales = lprice lndi lpimin IrwTrend wn;
  eval TrendPlusReg = IrwTrend + lprice + lndi + lpimin;
  score out=mylib.store;
run;
```

The score store is specified in the **OUT=** option of the **SCORE** statement (**score out=mylib.store;**). This score store, *mylib.store*, saves all the context information that is needed for continuing the forecasting process for the years after 1992, based on the fitted model and the history up to 1992.

The score store *mylib.store* is used to predict *lsales* in 1993 and 1994 for the following three scenarios:

Same price: In this scenario, the predictors retain their values from years 1991 and 1992; that is, the predictor values for 1991 are copied for 1993, and the predictor values for 1992 are copied for 1994. The data table to be scored is named *mylib.same*.

Low price: In this scenario, the predictor settings are as follows:

- For the year 1993, the values of disposable income (Indi) are the same as for 1991, and the values of lprice and lpimin are set to 3.15 for all regions.
- For the year 1994, the values of disposable income (Indi) are the same as for 1992, and the values of lprice and lpimin are set to 3.0 for all regions.

The data table to be scored is named mylib.low.

High price: In this scenario, the predictor settings are as follows:

- For the year 1993, the values of disposable income (Indi) are the same as for 1991, and the values of lprice and lpimin are set to 5.5 for all regions.
- For the year 1994, the values of disposable income (Indi) are the same as for 1992, and the values of lprice and lpimin are set to 6.0 for all regions.

The data table to be scored is named mylib.high.

The following statements create the data tables mylib.same, mylib.low, and mylib.high:

```
data mylib.same;
  set Cigar(where=(year >= '1jan1991'd));
  lsales = .;
  if year = '1jan1991'd then year = '1jan1993'd;
  else year = '1jan1994'd;
run;
data mylib.low;
  set Cigar(where=(year >= '1jan1991'd));
  lsales = .;
  if year = '1jan1991'd then do;
    year = '1jan1993'd;
    lprice = 3.15;
    lpimin = 3.15;
  end;
  else do;
    year = '1jan1994'd;
    lprice = 3.0;
    lpimin = 3.0;
  end;
run;
data mylib.high;
  set Cigar(where=(year >= '1jan1991'd));
  lsales = .;
  if year = '1jan1991'd then do;
    year = '1jan1993'd;
    lprice = 5.5;
    lpimin = 5.5;
  end;
  else do;
    year = '1jan1994'd;
    lprice = 6.0;
    lpimin = 6.0;
  end;
run;
```

The following statements show how to score these data tables by using the score store mylib.store:

```
proc cssm data=mylib.same;
  score in=mylib.store;
  output out=mylib.scoreSame;
run;

proc cssm data=mylib.low;
  score in=mylib.store;
  output out=mylib.scoreLow;
run;

proc cssm data=mylib.high;
  score in=mylib.store;
  output out=mylib.scoreHigh;
run;
```

In each case, the following are true:

- The data table to be scored is specified in the DATA= option in the PROC statement.
- The score store is specified by using the IN= option in the SCORE statement.
- An output table to save the scored rows is specified in the OUT= option in the OUTPUT statement.

Output 14.19.1 shows the forecasts for `lsales` for the first three regions (Alabama, Arkansas, and Arizona). This table is produced by merging the three output tables (`mylib.scoreSame`, `mylib.scoreLow`, and `mylib.scoreHigh`), by renaming the forecast variables, and by subsetting the rows suitably. As expected, the sales forecasts increase as the prices decrease.

Output 14.19.1 Forecasts under Different Price Settings

Cigarette Sales Forecasts under Different Price Settings

region	year	sales_highPrice	sales_samePrice	sales_lowPrice
Alabama	1993	4.59	4.73	5.26
Arizona	1993	4.19	4.33	4.87
Arkansas	1993	4.74	4.88	5.41
Alabama	1994	4.47	4.71	5.33
Arizona	1994	4.02	4.27	4.87
Arkansas	1994	4.65	4.87	5.50

Example 14.20: Monitoring Streaming Data Using Scoring

This example shows how you can use the scoring functionality to monitor a continuous stream of observations. The goal is to detect structural changes in the observation process as early as possible. For illustration purposes, the example uses the quarterly bivariate series (f_KSI, r_KSI), which is discussed in “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803. The variable f_KSI represents the quarterly average of the log of the monthly totals of front-seat passengers who are killed or seriously injured in car accidents, and r_KSI represents a similar number for rear-seat passengers. Recall that the `seatbelt` data set contains 16 years of series values, starting from the first quarter of 1969. This example uses the first 13 years—52 quarters—of data (through the last quarter of 1981) to fit a suitable model for the series and to create a score store that saves the context for later use. It is assumed that the fitted model continues to hold in the subsequent years. Monitoring of the process starts with the first quarter of 1982. The remaining 12 rows of the `seatbelt` data set are processed one by one and mimic a quarterly streaming data sequence. In real-world applications, the data source can be more general, and the observations could arrive at a much higher frequency, such as every minute.

Assume that the model for $y = (f_KSI, r_KSI)$ is

$$y_t = \mu_t + \zeta_t + \xi_t$$

where

- μ_t denotes a bivariate random walk. To capture the fact that f_KSI and r_KSI move together (that is, they are co-integrated), the covariance of the disturbance term of this random walk is assumed to be of less than full rank.
- ζ_t denotes a bivariate, time-invariant, trigonometric seasonal term.
- ξ_t denotes a bivariate white noise term.

This model is the same as the one used in “[Example 14.1: Bivariate Basic Structural Model](#)” on page 803, except that in this case no correction is made for the seat-belt law of 1983. In fact, the goal of this exercise is to determine, without the knowledge of this law, whether the level shift in the front-seat passenger series that is caused by this law can be detected during this monitoring.

The following DATA step loads the first 13 years of data into the table `mylib.train`:

```
data mylib.train;
    set seatBelt(obs=52);
run;
```

The following statements specify and fit the model, and save the scoring context in the store `mylib.inscore`:

```
proc cssm data=mylib.train opt(tech=activeset);
    id date interval=quarter;
    state error(2) type=WN cov(g);
    component wn1 = error[1];
    component wn2 = error[2];
    state level(2) type=RW cov(rank=1) checkbreak;
    component rw1 = level[1];
```

```

component rw2 = level[2];
state season(2) type=season(length=4);
component s1 = season[1];
component s2 = season[2];
model f_KSI = rw1 s1 wn1;
model r_KSI = rw2 s2 wn2;
output break(alpha=0.01) ao(alpha=0.01);
score out(10)=mylib.inscore;
run;

```

Note that because the `OUT(k)=` form of the `OUT` option is used in the `SCORE` statement (`score out(10)=mylib.inscore;`), the `mylib.inscore` store retains the context information from the last 10 quarters (from 1979/3 to 1981/4). The score store also retains the structural break detection settings that are specified in the `STATE` statement for `level`, and it retains the significance levels for the additive outlier detection and structural break detection that are specified in the `OUTPUT` statement.

After the model fitting and the initial score-store creation, the monitoring of streaming data is done using the following steps:

- Starting with 1982/1 (which happens to be the 53rd row of `seatbelt`), successive quarters are loaded into the `mylib.nextObs` table one at a time; that is, `mylib.nextObs` always has only one row.
- Each quarter is scored by using the `mylib.inscore` store and, additionally, an output score store (`mylib.outscore`) is created that incorporates the information in the current observation (`score in=mylib.inscore out=mylib.outscore;`).
- The two score stores, `mylib.inscore` and `mylib.outscore`, are swapped so that `mylib.outscore` becomes the input score store for the next observation.

The following macro, `%STREAM`, performs these three steps:

```

%macro STREAM;
  %do i=53 %to 64;
    /* read the next row */
    data mylib.nextObs;
      set seatBelt(firstobs=&i obs=&i);
    run;
    /* score the row that is read */
    proc cssm data=mylib.nextObs;
      ods output AOSummary=ao&i;
      ods output StateElementBreakSummary=ls&i;
      %if &i = 53 %then %do;
        ods output IdInformation=idInfo;
        ods output ResponseInfo=respInfo;
      %end;
      score in=mylib.inscore out=mylib.outscore;
    run;
    /* swap inscore and outscore */
    proc cas;
      table.altertable/name="outscore", rename="tmp";
      table.altertable/name="inscore", rename="outscore";
      table.altertable/name="tmp", rename="inscore";
    run;
  %end;
%macroend;

```

```

quit;
%end;
%mend;

%STREAM;

```

For each new quarter, the %STREAM macro saves the results, if any, of the additive outlier detection and the structural break detection in SAS data sets (`ods output AOSummary=ao&i;` and `ods output StateElementBreakSummary=ls&i;`). For the first quarter, the ID information table and the response information table are also saved. The ID information table for the first quarter (1982/1) is shown in [Output 14.20.1](#). Note that even though the input table (`mylib.nextObs`) has just one observation (which corresponds to 1982/1), PROC CSSM processed 11 observations (from 1979/3 to 1982/1). This is because, internally, PROC CSSM works with a data set that is created by combining the information from the previous 10 quarters (1979/3 to 1981/4) that is present in the input score store and the one quarter (1982/1) that is present in the current input data table (`mylib.nextObs`).

Output 14.20.1 ID Variable Information at Start of Scoring

ID Variable Information

Name	Start	End	NumberDistinct	MaximumDelta	Type
date	1979/3	1982/1	11	1.0000	Regular

For the same reason, [Output 14.20.2](#) also shows the response variable information for 11 quarters.

Output 14.20.2 Response Variable Information at Start of Scoring

Response Variable Information

Name	NObs	NMiss	InducedNMiss	Minimum	Maximum	Mean	StdDev
f_KSI	11	0	0	6.464	6.799	6.663	0.1147
r_KSI	11	0	0	5.635	6.119	5.914	0.1610

The outlier detection and the structural break detection, which are performed after the arrival of each new quarterly observation, are also performed on the set of 11 observations that is formed by the current observation and the observations in the 10 previous quarters. It happens that no additive outliers or structural breaks are detected in the four quarters of 1982. However, starting with the first quarter of 1983 (when the seat-belt law is introduced), additive outliers and structural breaks are detected in each quarter. The aggregate summary of this detection activity (obtained by combining the following pairs of data sets: `ao57` with `ao64` and `ls57` with `ls64`) is shown in two tables: [Output 14.20.3](#) shows the results of break detection for the bivariate state, level, and [Output 14.20.4](#) shows the results of the additive outlier detection. In both tables, an extra column, `obs_date`, is added to indicate the quarter that is associated with the observation that was scored. In addition, two more columns, `zValue` ($= \text{Estimate}/\text{StdErr}$) and `ProbZ` (the corresponding p -value), are added to the additive outlier table for ease of comparison with the break detection table. An examination of the two tables shows the following:

- When the observation that is associated with the first quarter of 1983 is processed, an additive outlier is flagged for `f_ksi` and a structural break is flagged at the first element of the bivariate state, level, both at time 1983/1. Recall that the first element of level corresponds to `f_ksi`. The associated Z-score, -7.66 ,

is the same in both cases. This makes sense, because at this point it is difficult to determine whether the unusually low `f_ksi` value is attributable to a shift in the level or is simply a one-time change.

- When the observation that is associated with the second quarter of 1983 is processed, 1983/1 is again flagged as an additive outlier for `f_ksi` and as a structural break for the first element of `level`. The only difference is that the evidence of a structural break has become stronger than before (more extreme Z-score: -9.23), whereas the evidence for an additive outlier has weakened (less extreme Z-score: -5.67).
- When the observation that is associated with the third quarter of 1983 is processed, 1983/1 continues to be flagged as a structural break for the first element of `level`, but it is no longer the most extreme additive outlier for `f_ksi`. Instead, 1983/1 is flagged as an additive outlier for `r_ksi`, because it has a larger value than expected! This is understandable because, as the model shows, `f_KSI` and `r_KSI` move together, so the 1983/1 value of `r_ksi` should have been lower than the observed value.
- As more observations are processed, the evidence that 1983/1 is the location of the level shift in `f_KSI` keeps getting stronger.

In real-world applications, when sufficient evidence for a break is gathered, the monitoring is paused and some appropriate action is taken.

Output 14.20.3 Level Shift Detection during Monitoring of 1982/1 to 1984/4

Detection of Break in the Bivariate State: Level

obs_date	Time	StateBreak	ElementIndex	zValue	ProbZ
1983/1	1983/1	level	1	-7.66	<.0001
1983/2	1983/1	level	1	-9.23	<.0001
1983/3	1983/1	level	1	-10.50	<.0001
1983/4	1983/1	level	1	-11.60	<.0001
1984/1	1983/1	level	1	-13.17	<.0001
1984/2	1983/1	level	1	-14.43	<.0001
1984/3	1983/1	level	1	-15.10	<.0001
1984/4	1983/1	level	1	-16.12	<.0001

Output 14.20.4 Additive Outlier Detection during Monitoring of 1982/1 to 1984/4

Detection of Additive Outliers

obs_date	Time	Name	Estimate	StdErr	zValue	ProbZ

Example 14.21: Simulation-Smoothing-Based Sampling Distribution of the Sum of Forecasts

This example shows how you can use the CSSM procedure to derive the sampling distribution of a complicated function of the forecasts of a response variable by using simulation smoothing. (For more information, see the section “[Simulation Smoothing](#)” on page 787.) The example uses the well-known airline passenger series, given as Series G in (Box and Jenkins 1976), and the equally well-known model of it, the Airline model. This series is a monthly series that consists of the number of airline passengers who traveled during the years 1949 to 1960. The data set `sashelp.air` contains this series (`air`) along with the date variable (`date`). The Airline model postulates an ARIMA (autoregressive, integrated, moving average) model for the logarithm of the air series (`logAir`). That is, the modeling is done in the log scale. However, often the results of the modeling are needed in the original scale. For example, you might want to obtain a model-based confidence interval for the total number (sum of 12 months) of airline passengers in some future year. The following steps summarize how to do this by using simulation smoothing:

1. Use PROC CSSM to fit the Airline model to the `logAir` series by using the first 11-year span of the data (1949 through 1959), and obtain the model-based forecasts of `logAir`, denoted by `forecast_logAir`, for the 12 months of 1960. The actual data for the months in 1960 are withheld from the fitting and forecasting phases and reserved for the “sanity check” at the end of the analysis.
2. Save the fitted model for its subsequent use in simulation smoothing by using the `OUTMODEL=` option in the `SIMSMOOTH` statement.
3. Let $\text{TotalAir1960} = \sum_{\text{Jan1960}}^{\text{Dec1960}} \exp(\text{forecast_logAir})$. `TotalAir1960` is a point forecast of the total number of airline passengers in 1960, based on the data from 1949 to 1959. Because it is a sum of the exponential of `forecast_logAir` for different months of 1960 that are also correlated, its sampling distribution is analytically intractable. Simulation smoothing is applicable in precisely such situations.
4. Using PROC CSSM again with the `SIMSMOOTH` statement, generate 1,000 random draws of the forecasts of `logAir` (`forecast_logAir`) for the 12 months of 1960. Using the `OUTPRED=` option, save these draws to an output table for postprocessing.
5. Using the generated 1,000 draws of `forecast_logAir`, obtain 1,000 draws of `TotalAir1960`. These are used to obtain the simulation-based sampling distribution of `TotalAir1960`.

The remainder of this example shows the SAS code for carrying out these steps and the results that they produce. The following DATA step creates a data set, `mylib.air`, from `sashelp.air` such that it has the log-transformed passenger series (`logAir`); `logAir` is set to missing during 1960 so that PROC CSSM produces forecasts and later the simulations for that period:

```
data mylib.air;
    set sashelp.air;
    if year(date) < 1960 then logAir = log(air);
    else logAir = .;
run;
```

The following statements fit the Airline model (ARIMA(0,1,1)(0,1,1)12) to the `logAir` series and save the model in the BLOB table `mylib.airModel`:

```
proc cssm data=mylib.air;
  id date interval=month;
  deplag airDiffs(logAir) logAir(lags=(1 12 13) coeff=(1 1 -1));
  trend ma(arma(q=1 sq=1 s=12));
  model logAir = airDiffs ma;
  simsmooth outmodel=mylib.airModel;
run;
```

The following statements use the fitted model that is saved in the mylib.airModel table and the input data table mylib.air to generate the desired simulations:

```
proc cssm data=mylib.air;
  simsmooth inmodel=mylib.airModel seed=1 nsim=1000
    outpred=mylib.airPred;
run;
```

Output 14.21.1 shows the summary of the simulation smoothing process.

Output 14.21.1 Simulation Smoothing of logAir Predictions

Simulation Smoothing Summary	
Input Data Table	AIR
Model Store	AIRMODEL
Number of Simulations	1000
Random Number Seed Sequence	1 : 1000
Simulated Response Predictions Table	AIRPRED

Because of the option NSIM=1000, PROC CSSM produces 1,000 draws of predictions of logAir for the 12 months of 1960. The simulated predictions are output to a table, mylib.airPred, for postprocessing. In total, mylib.airPred contains 1,001 sets of values (12 rows for each set that correspond to the months of 1960):

- One set of 12 rows, which is assigned a seed value of -1, contains the usual model-based predictions for logAir.
- The other 1,000 sets of 12 rows, with a seed value of 1 through 1,000 (because of the options SEED=1 and NSIM=1000), contain the simulations of predictions of logAir.

The table mylib.airPred has three columns: SEED contains the seed values, Date contains the observation dates, and SimSmooth_logAir contains the actual predictions or their simulations. The following statements create a data set, yearly, that contains the 1,000 draws of $\text{TotalAir}_{1960} = \sum_{\text{Jan1960}}^{\text{Dec1960}} \exp(\text{forecast_logAir})$.

```
data airPred;
  set mylib.airPred;
  where seed > -1;
  simAir = exp(simsmooth_logAir);
run;
proc sort data=airPred;
  by seed date;
run;
proc means data=airPred noprint;
  by seed;
```

```
var simAir;
output out=yearly sum=TotalAir1960;
run;
```

The following statements compute the actual total number of passengers in 1960, which turns out to be 5,714:

```
proc means data=sashelp.air sum;
  where year(date)=1960;
  var air;
run;
```

By using the 1,000 draws of TotalAir1960 in the yearly table, you can easily obtain a variety of simulation-based measures of sampling distribution of TotalAir1960. For example, [Output 14.21.2](#) shows the mean, median, and a few percentiles of the sampling distribution of TotalAir1960, which is generated by the following statements:

```
proc summary data=yearly print p1 q1 mean median q3 p99;
  var TotalAir1960;
run;
```

Output 14.21.2 A Few Percentiles of the Sampling Distribution of TotalAir1960

Analysis Variable : TotalAir1960					
	Lower			Upper	
1st Pctl	Quartile	Mean	Median	Quartile	99th Pctl
5132.71	5653.00	5876.41	5862.91	6102.39	6657.69

The table shows that the mean (5876.4) and the median (5862.9) of the sampling distribution are quite close to the actual total (5714) observed in 1960. Moreover, the interval (5133, 6658) can serve as a 98% confidence band for the total number of passengers in 1960. Finally, the following statements generate the graph shown in [Output 14.21.3](#), which displays the sampling distribution of TotalAir1960:

```
proc sgplot data=yearly;
  title Sampling Distribution of TotalAir1960;
  histogram TotalAir1960;
  density TotalAir1960 / legendlabel="Normal" name="Normal";
  refline 5714.00 / axis=x lineattrs=GraphFit2
    legendlabel="Actual Total in 1960" name="Coeff";
  discreteLegend "Normal" "Coeff" / across=1 location=inside;
run;
```

Output 14.21.3 Histogram of TotalAir1960

Overview: DEEPCAUSAL Procedure

The DEEPCAUSAL procedure estimates the average causal effect and performs policy evaluation and policy comparison by using deep neural networks (DNNs). DNNs overcome several technical difficulties in the big data era, including the following:

- the huge amount of discrete or continuous potential covariates
- the unknown nonlinear relationships among the covariates, the outcome, and the treatment assignment

A problem in applying DNN to causal inference is interpretability. To solve this problem, the DEEPCAUSAL procedure applies the DNNs via a two-step semiparametric framework (see the section “[Details: The DEEPCAUSAL Procedure](#)” on page 931) and gives inferential results for the parameters of interest through the corresponding influence functions.

The DEEPCAUSAL procedure can estimate 11 types of causal effects (or parameters of interest). These include full-population causal effects, such as the average treatment effect (ATE), and subpopulation causal effects, such as the average treatment effect for the treated (ATT) and the average treatment effect for the untreated (ATU). For more information, see the sections “[Full-Population Average Effect Parameters](#)” on page 934 and “[Subpopulation Average Effect Parameters](#)” on page 936. The DEEPCAUSAL procedure can also perform policy evaluation and policy comparison. For more information, see the section “[Policy Evaluation and Comparison](#)” on page 937. PROC DEEPCAUSAL supports the SCORE statement, which enables you to save the causal model specifications and estimation results for scoring and policy evaluation and comparison without needing to reestimate the DNNs for these models.

Tools for causal analysis of nonrandomized data are available in the following procedures:

- The CAUSALGRAPH procedure enables you to analyze graphical causal models and to construct sound statistical strategies for causal effect estimation. For more information, see Chapter 37, “The CAUSALGRAPH Procedure” (*SAS/STAT User’s Guide*).
- The PSMATCH procedure enables you to perform propensity score analyses and to assess covariate balance. For more information, see Chapter 101, “The PSMATCH Procedure” (*SAS/STAT User’s Guide*).
- The CAUSALTRT procedure enables you to perform estimation of a causal effect. For more information, see Chapter 39, “The CAUSALTRT Procedure” (*SAS/STAT User’s Guide*).
- The CAUSALMED procedure enables you to decompose a (total) causal effect into direct and indirect effects. For more information, see Chapter 38, “The CAUSALMED Procedure” (*SAS/STAT User’s Guide*).
- The MODEL, PANEL, QLIM, and TMODEL procedures in SAS/ETS and the CPANEL and CQLIM procedures in SAS Econometrics support endogenous variables and instrumental variables. For more information, see Chapter 24, “MODEL Procedure” (*SAS/ETS User’s Guide*), Chapter 25, “PANEL Procedure” (*SAS/ETS User’s Guide*), Chapter 27, “QLIM Procedure” (*SAS/ETS User’s Guide*), Chapter 39, “TMODEL Procedure” (*SAS/ETS User’s Guide*), Chapter 11, “CPANEL Procedure,” and Chapter 12, “CQLIM Procedure.”

- The VARMAX procedure supports Granger causality tests. For more information, see Chapter 42, “VARMAX Procedure” (*SAS/ETS User’s Guide*).

PROC DEEPCAUSAL requires SAS Cloud Analytic Services (CAS) in order to run, and it does the following:

- enables you to run on a cluster of machines that distribute the data and the computations
- exploits all the available cores and concurrent threads

Using CAS Sessions and CAS Engine Librefs

SAS Cloud Analytic Services (CAS) is the analytic server and associated cloud services in SAS Viya. This section describes how to create a CAS session and set up a CAS engine libref that you can use to connect to the CAS session. It assumes that you have a CAS server already available; contact your system administrator if you need help starting and terminating a server. This CAS server is identified by specifying the host on which it runs and the port on which it listens for communications. To simplify your interactions with this CAS server, the host information and port information for the server are stored as SAS option values that are retrieved automatically whenever this CAS server needs to be accessed. You can examine the host and port values for the server at your site by using the following statements:

```
proc options option=(CASHOST CASPORT);
run;
```

In addition to starting a CAS server, your system administrator might also have created a CAS session and a CAS engine libref for your use. You can define your own sessions and CAS engine librefs that connect to the CAS server as shown in the following statements:

```
cas mysess;
libname mylib cas sessref=mysess;
```

The CAS statement creates the CAS session named `mysess`, and the LIBNAME statement creates the `mylib` CAS engine libref that you use to connect to this session. It is not necessary to explicitly name the CASHOST and CASPORT of the CAS server in the CAS statement, because these values are retrieved from the corresponding SAS option values.

If you have created the `mysess` session, you can terminate it by using the TERMINATE option in the CAS statement as follows:

```
cas mysess terminate;
```

For more information about the CAS and LIBNAME statements, see the section “[Introduction to Shared Concepts](#)” on page 54 in Chapter 4, “[Shared Concepts](#).”

Getting Started: DEEPCAUSAL Procedure

This section provides an example that the DEEPCAUSAL procedure supports.

Simulation Study

This example illustrates how the DEEPCAUSAL procedure estimates the parameters of interest and performs policy evaluation and policy comparison. It also demonstrates how you can save the model information and use it later to score other new data. A simulated data set is generated, based on the following assumptions:

- The treatment variable, denoted by T , is binary (0 or 1).
- The outcome variable, denoted by Y , is continuous.
- There are 20 covariates: $x_j \sim \text{Uniform}(0, 1)$ for $j = 1, \dots, 20$.
- Four of the covariates are randomly selected and used in the outcome model. The first selected variable is used in the propensity score model.

The outcome model is given as

$$Y = \alpha(\mathbf{X}) + \beta(\mathbf{X})t + \epsilon, \quad \epsilon \stackrel{\text{iid}}{\sim} N(0, 1)$$

$$\alpha(X) = 1 + \cos(2\pi \sum_{i=1}^4 w_i x_{s_i})$$

$$\beta(X) = \sin(2\pi \sum_{i=1}^4 w_i x_{s_i})$$

where $\{s_i\}_{i=1}^4$ denotes the indices of the four covariates that are randomly selected from the 20 covariates and $\mathbf{X}$ denotes the covariates vector $\{x_j\}_{j=1}^{20}$.

The propensity score model is given as

$$\Pr(T = 1 | \mathbf{X} = \mathbf{x}) = p(\mathbf{x}) = 0.1 + 0.8 \sin(2\pi |x_{s_1} - 0.5|)$$

where T denotes the treatment variable.

The following statements simulate 20,000 samples that are based on the propensity score and outcome models that were just presented:

```
%macro deepEconGenerateData(n,d,eff,seed);
  data deepEconDGP;
    array x[&d.] x1-x&d.;
    array w[&d.] w1-w&d.;
    array selectedX[&eff.] selectedX1-selectedX&eff.;
    retain w;
    call streaminit('pcg', &seed.);
    * weights;
```

```

    sumw = 0;
    do i = 1 to &eff.;
        w[i] = rand('Uniform');
        sumw = sumw + w[i];
    end;
    do i = 1 to &eff.;
        w[i] = w[i] / sumw;
    end;
    * select x;
    do i = 1 to &eff.;
        selectedX[i] = ceil(&d.*rand('Uniform'));
    end;
    do i = 1 to &n.;
        * covariates;
        do j = 1 to &d.;
            x[j] = rand('Uniform');
        end;
        * treatment assignment;
        u = rand('Uniform');
        sumx = 0;
        do j = 1 to &eff.;
            sumx = sumx + w[j]*x[selectedX[j]];
        end;
        px = (0.1 + 0.8*sin(2*abs(x[selectedX[1]]-0.5)*3.1415926));
        if(u<=px) then t=1;
        else t=0;
        * outcome;
        eps = rand('Normal');
        mu = 1 + cos(sumx*2*3.1415926);
        tau = sin(sumx*2*3.1415926);
        y = mu + tau*t + eps;
        s1=(tau>0);
        s0=1-s1;
        output;
    end;
run;
%mend;

%let n=20000;
%let d=20;
%let eff=4;
%let seed=12346;
%deepEconGenerateData(&n., &d., &eff., &seed.);

```

The following DATA steps load the first 10,000 observations in the data set `deepEconDGP` into the data table `simCausal_train` and the second 10,000 observations into the data table `simCausal_test` in your session that is associated with the mylib libref. The DATA step assumes that your libref is named mylib, but you can substitute any appropriately defined libref.

```

data mylib.simCausal_train;
    set deepEconDGP(obs=10000 keep=i x1-x20 t y px mu tau s0 s1
                    selectedX1-selectedX4);
run;

```

```
data mylib.simCausal_test;
  set deepEconDGP(firstobs=10001 keep=i x1-x20 t y px mu tau s0 s1
    selectedX1-selectedX4);
run;
```

The unknown functions $p(\cdot)$, $\alpha(\cdot)$, and $\beta(\cdot)$ are estimated through two DNNs by using the data set `simCausal_train`. The parameters of interest, policy evaluation, and policy comparison are then estimated. The following statements use PROC DEEPCAUSAL to get these estimates and store the model information and parameter learning results:

```
proc deepcausal data=mylib.simCausal_train;
  id i;
  psmodel t=x1-x20 / dnn=(nodes=(32 32 32 32)
    train=(optimizer=(miniBatchSize=2000 regL1=0.0001 maxEpochs=1000
      algorithm=adam(learningRate=0.0001)) nthreads=5 seed=12345));
  model y=x1-x20 / dnn=(nodes=(32 32 32 32)
    train=(optimizer=(miniBatchSize=2000 regL1=0.001 maxEpochs=1000
      algorithm=adam) nthreads=5 seed=12345));
  infer policy=(s1 s0) policyComparison=(base=(t) compare=(s0 s1))
    out=mylib.oest outdetails=mylib.odetails;
  score outps=mylib.outpsdata outa=mylib.outadata outb=mylib.outbdata;
run;
```

The OUTPS= option writes the propensity score model information to the data table `outpsdata`, the OUTA= option writes the $\alpha(\cdot)$ estimation information to the data table `outadata`, and the OUTB= option writes the $\beta(\cdot)$ estimation information to the data table `outbdata`. The number of observations is shown in Figure 15.1.

Figure 15.1 Number of Observations

The DEEPCAUSAL Procedure

Number of Observations	10000
Observations with Missing Covariates	0
Observations with Missing Covariates for PS Model	0
Observations with Missing Covariates for Outcome Model	0
Observations with Missing Outcome	0

The estimates of parameters of interest are shown in Figure 15.2.

Conditional Average	1	0	0.368315	0.018645	0.331772	0.404859	19.75	<.0001
Conditional Average	1	1	0.356500	0.016645	0.323877	0.389123	21.42	<.0001
ATT		1	0.012292	0.022012	-0.030850	0.055435	0.56	0.5765
ATU		0	0.004766	0.023280	-0.040863	0.050394	0.20	0.8378
Composition Effect	1		-0.011815	0.017386	-0.045891	0.022261	-0.68	0.4968
Observed Difference			-0.007049	0.024815	-0.055686	0.041587	-0.28	0.7764

The policy evaluation estimates the expected utility of a policy. The policy evaluation results are shown in Figure 15.3.

Figure 15.3 Policy Evaluation

Policy Evaluation						
Policy	Estimate	Standard Error	95% Confidence Limits		Z	Pr > Z
s1	0.653567	0.015892	0.622419	0.684715	41.13	<.0001
s0	0.059585	0.015050	0.030087	0.089083	3.96	<.0001

The policy comparison estimates the difference in expected utility of two policies. The policy comparison results are shown in Figure 15.4.

Figure 15.4 Policy Comparison

Policy Comparison						
Comparison Policy	Base Policy	Estimate	Standard Error	95% Confidence Limits		Z Pr > Z
s0	t	-0.306508	0.015133	-0.336168	-0.276848	-20.25 <.0001
s1	t	0.287473	0.014791	0.258483	0.316464	19.44 <.0001

You can apply the previously saved propensity score model, the $\alpha(\cdot)$ estimation information, and the $\beta(\cdot)$ estimation information to a new data set by specifying the INPS=, INA=, and INB= options in the SCORE statement. The following statements use the outpsdata, outadata, and outbdata data tables as input data tables and estimate the parameters of interest, policy evaluation, and policy comparison by using the simCausal_test data set:

```

proc deepcausal data=mylib.simCausal_test;
  id i;
  infer policy=(s1 s0) policyComparison=(base=(t) compare=(s0 s1))
    out=mylib.oest2 outdetails=mylib.odetails2;
  score inps=mylib.outpsdata ina=mylib.outadata inb=mylib.outbdata;
run;

```

When you specify the INPS=, INA=, and INB= options in the SCORE statement, you do not need to specify the PSMODEL or MODEL statement. The estimates of parameters of interest, policy evaluation, and policy comparison are shown in [Figure 15.5](#).
